Digestives.—Digestives are medicines that act directly upon the food in the digestive organs, causing it to digest more rapidly and perfectly. They are used when the stomach is unable to secrete a sufficient quantity of gastric juice, or when the juice secreted has an abnormal composition. The digestive power of the gastric juice depends upon the presence of hydrochloric acid and pepsin. If either one of these be deficient, digestion may become tardy and imperfect, and the symptoms of dyspepsia supervene. Recently cases have been reported in which digestion seemed perfect, although no trace of free hydrochloric acid could be detected in the gastric contents. In other cases prolonged superacidity was found without any notable gastric disorder.

Hydrochloric acid is sometimes secreted in insufficient quantity in cases of atonic dyspepsia. Usually the bitter tonics, especially the preparations containing alcohol, excite a more abundant secretion, and hence suffice to allay the symptoms of defective digestion. But sometimes the symptoms persist notwithstanding their proper and continued use. When this is the case, recourse should be had to hydrochloric acid, which is generally followed by rapid improvement.

It is best, as a rule, to administer the acid soon after meals, and, if necessary, to repeat the dose once or twice at intervals of two hours.

Some writers hold that in cases of dyspepsia in which acid eructations frequently occur, the acid should be given before meals, as by its astringent action upon the gastric mucous membrane it will tend to diminish the excessive secretion of acid. The presence of an excess of acid in the stomach during the digestive process is usually due to fermentation which gives rise to abnormal acids; generally the administration of hydrochloric acid after meals prevents such fermentation. Should, however, this method of administration fail to give relief, the acid may be given before meals, as, of course, it is not impossible that an excess of it may be secreted.

The dose of the official dilute hydrochloric acid may vary from ten to thirty drops. It should be diluted with several ounces of water, and may be given in mixture with a bitter tincture and a small quantity of syrup. ℞ Acid. hydrochlor. dil., ʒ ij.; tinct. gentian. comp., syrup. aurant., āā ℥ i.; aq. destill., q.s. ad ℥ vi. M. Sig.: A tablespoonful after meals.

Pepsin, like hydrochloric acid, is essential for normal digestion. But, inasmuch as it is a ferment, a small amount may suffice to digest very large quantities of albumen if there be constantly present a sufficient quantity of acid. As a digestive it is indicated when the stomach is unable to secrete a sufficient amount; but it is impossible to state when this is the case. The contents of the stomach of dyspeptic patients, removed at various intervals after meals, were rarely found to digest fibrin more rapidly after the addition of pepsin, while this almost invariably took place after the addition of hydrochloric acid (Leube). So, also, the contents of the stomach of typhoid-fever patients, while constantly found destitute of hydrochloric acid, always seemed to contain a sufficient amount of pepsin (Gluzinski). Hence, in cases of dyspepsia, if hydrochloric acid, properly given, have failed to improve digestion, pepsin may be used together with the acid. The dose of pepsin is about ten grains, and is administered soon after meals. The official solution of pepsin, containing some hydrochloric acid, is given in doses of half an ounce.

Extract of malt, when properly prepared, contains a small quantity of diastase, and hence may promote the digestion of amylaceous food. For this purpose it may be taken with the meals, in quantities of one to four drachms, either alone or mixed with milk, bouillon, or wine. It has been recommended as a nutrient in wasting diseases, but should not be employed unless it is not possible to administer more useful s 'bstances.

Pancreatin has been recommended in cases of imperfect intestinal digestion. It is doubtful whether it can pass through the stomach without losing its activity. In some cases of dyspepsia it has been found to give relief when administered together with a little soda about two hours after meals.

Papain, a ferment obtained from the juice of *carica papaya*, digests fibrin and albumen more readily than pepsin does, and has therefore been recommended in dyspepsia in doses of five to ten grains.

HÆMATINICS.—This term is applied to medicines that increase the coloring matter of the blood, the hæmoglobin. The most important of these are the preparations of iron or the

Chalybeates.—Iron is an efficient remedy in most forms of anæmia. Usually the symptoms due to the defective state of the blood gradually vanish when it is properly administered for some weeks; the integuments lose their waxy pallor and resume a healthy glow; the pulse again becomes full and forcible; the vertigo and headache cease; and the languor and depression give way to the normal strength and vigor. This remarkable action was observed long before it was known that iron is a component of the hæmoglobin of the red blood corpuscles. Since it has been ascertained that a diminution of the coloring matter of the blood indicates a deficiency of iron, it has been held that chalybeates cure anæmia by supplying material necessary for the rapid regeneration of the red blood corpuscles.

It is generally supposed that the preparations of iron produce little or no effect in healthy persons, if given in such forms as not to cause serious gastric disorder. But careful observations recently made (see *Therapeutische Monatshefte*, Bd. ii., p. 11, 1888) show that even minute doses of chloride of iron, repeated day after day for several weeks, may induce notable disorder of the stomach, accelerate the heart's action, and cause severe attacks of dyspnœa, a feeling of general heat, occasional flushing of the face, itching of the skin, acneiform eruptions, and slight conjunctivitis.

In anæmia, if the cause of the defective state of the blood be irremediable, iron fails to produce any marked or permanent increase of the red blood corpuscles. Hence its use in chronic wasting diseases and in organic affections is generally futile. Its utility is most strikingly manifested in chlorosis; often a steady increase of the hæmoglobin from day to day is observed, and in a few weeks the blood again contains the normal number of red blood corpuscles. It is also very efficient, though usually less essential, in the anæmia remaining after severe acute diseases and after hemorrhages; but is almost powerless in pernicious or idiopathic anæmia.

In all cases of anæmia it is essential for success in the use of iron that all the circumstances influencing nutrition be favorable; that the patient have a plain nutritious diet, that he take a sufficient amount of bodily exercise, that he spend a considerable part of each day in the open air, and that he be regular in all his habits.

Iron is contraindicated as a hæmatinic when the temperature is abnormally elevated, when there is present an organic disease of the stomach, or any affection of the lungs attended with congestion of the pulmonary circulation.

The official preparations of iron are excessively numerous, and young practitioners are often in doubt as to the most efficient ones. When the object is simply to hasten the regeneration of the red blood corpuscles, it is immaterial which preparations are selected, as all, if given in such doses and forms as not to disorder the digestive organs, act equally well.

The dose should be small, even of those preparations which have little local action. The quantity of iron contained in the food daily consumed by a vigorous person is about one grain; it is doubtful whether a much larger quantity can be assimilated when iron is given as a medicine. It may be observed, even when small doses are given, that the greater part is not absorbed and is voided with the fæces.

The preparations most frequently used are reduced iron, saccharated carbonate, mass of carbonate, citrate, pyrophosphate, iodide, and tincture of the chloride.

Reduced iron is given in doses of one to two grains, generally in pill or powder. ℞ Ferri reducti, 5.0 (gr. lxxv.); pulv. rad. althææ, 4.0 (ʒ i.); gelatin., q.s. ut ft. pil. No. 90. Sig.: At first one and gradually two or three pills three times daily. If properly prepared these pills are soft, and hence well borne by the stomach (Leube). ℞ Ferri reducti, gr. xij.; sacch. albi, ʒ i.; ol. menth. pip., gtt. ij. M. Div. in part. æqual. xij. Sig.: One powder after each meal.

Saccharated carbonate of iron is given in doses of from five to ten grains. In cases of atonic dyspepsia with anæmia, it may be given together with quinine as follows: ℞ Ferri carb. sacch., ʒ i.; quin. sulph. gr. xij. M. Div. in part. æq. No. xij. Sig.: One powder after each meal. It may also be administered in the form of an effervescent draught as follows: ℞ Ferri carb. sacch., sodii bicarb., āā ℈ iv. M. Div. in part. æqual. viij. Sig.: No. 1. ℞ Acid. tartarici, ℈ ij.; sacch. albi, ℈ ij.; ol. limonis, gtt. ij. M. Sig. No. 2. Dissolve one powder of No. 1 in some water, add one powder of No. 2, and drink while effervescing.

Mass of carbonate of iron is given in pill. It is frequently ordered together with quinine as follows: ℞ Quin. sulph., gr. x.; mass. ferri carb., ℈ ij. M. Ft. pil. No. xx. Sig.: One or two pills after meals.

Citrate of iron is usually ordered in solution, and sometimes in powders and pills. The bitter wine of iron is an excellent preparation in atonic dyspepsia and anæmia, given in doses of one or two teaspoonfuls after meals. Pyrophosphate of iron is given like the citrate, in doses of five to ten grains after meals, usually in solution.

The syrup of the phosphates of iron, quinine, and strychnine is frequently employed in atonic dyspepsia and anæmia, in doses of one or two teaspoonfuls.

The tincture of chloride of iron contains about five per cent. of metallic iron. It is given in cases requiring an astringent preparation, in doses of ten to thirty drops, largely diluted. Glycerin modifies its taste very markedly. ℞ Tinct. ferri chlor., ʒ ij.; glycerini, ʒ xiv. M. Sig.: A teaspoonful in a wineglassful of water after meals.

GENERAL TONICS.—Some general tonics act chiefly as nutrients, gradually increasing the weight of the body, and invigorating all the organs by supplying needed material; others seem to exert a stimulating or modifying action upon the tissues, in consequence of which they assimilate the nutritive material of the blood more rapidly.

Cod-liver Oil.—In chronic wasting diseases and in various kinds of malnutrition, cod-liver oil displays remarkable power. Usually it improves the appetite, invigorates the digestive organs, augments the number of red blood corpuscles, and increases the body weight.

Besides the ordinary constituents of oil, it contains free fatty acids, the quantity varying with the kind of oil. According to a recent analysis, the quantity of free oleic acid in the pale variety of oil varies from 0.18 to 0.71 per cent., and in the dark variety from 2.54 to 5.07 per cent. Cod-liver oil contains also traces of iodine, bromine, chlorine, phosphorus, sulphur, ammonia, and trimethylamin, and the dark variety, biliary matter.

The superior digestibility of cod-liver oil has recently been satisfactorily explained (Buchheim, 1874). It had long been observed that this oil diffuses itself through animal membranes more rapidly than do other oils. As the presence of bile greatly increases the diffusibility of other oils, and the early analyses of cod-liver oil had shown the presence of bile in it, the remarkable digestibility of the oil was attributed to the biliary matter. But Buchheim showed that the pale oil contains no bile, and that its digestibility is solely due to the free fatty acids. The modifying influence of the fatty acids can be readily observed by placing a small amount of dilute solution of soda (3 to 1,000) in a test tube and adding a few drops of cod-liver oil. In a very short time the mixture becomes milky, the union between the soda and the fatty acids completely emulsifying the oil.

It is well known that all fats and oils, before they can be absorbed, must undergo a similar process in the small intestine. This is accomplished chiefly through the influence of the pancreatic juice, which contains a peculiar ferment having the power to decompose fats into glycerin and free fatty acids. The free fatty acids, coming into contact with the alkali present in the intestinal juices are quickly saponified and thus enabled to emulsify any undecomposed fat.

Cod-liver oil, containing free fatty acids, becomes emulsified more readily than other fats in the alkaline intestinal juice; hence many persons, who are soon disordered by other fats, perhaps from defective secretion of pancreatic juice, readily digest cod-liver oil.

Perhaps the utility of cod-liver oil is not fully explained by its great digestibility; it may after absorption differ in action from other fats. It is said to have been observed in horses that the fat laid on from corn is tolerably permanent, while that produced by feeding on grass is soft and quickly disappears when the animal is put to work (Brunton). Possibly cod-liver oil is so useful in some wasting diseases by promoting the growth of cells more rapidly than do other fats and oils. It certainly, in many cases of anæmia, rivals iron in the rapidity with which it causes an increase in the number of red blood corpuscles.

Cod-liver oil is indicated in all chronic diseases attended by anæmia and emaciation. It has been found, by the most careful observers, to be the best means of sustaining and increasing nutrition in chronic pulmonary affections, especially phthisis and chronic bronchitis. Often, soon after its use is begun, the symptoms of phthisis greatly abate, and in some cases, when little pulmonary tissue is invaded and injured, a complete cure results. It is also successfully employed in debility of the nervous system resulting from prolonged overwork, and in hysteria and neuralgia. Usually it is strikingly beneficial in diseases of the bones, rickets, chronic rheumatism, and tertiary syphilis; in malnutrition of the heart with defective general circulation, and in scrofulous affections of the glands, mucous membranes, skin, and bones.

The dose of the oil should at first be small, about a teaspoonful. As soon as the stomach has become accustomed to it, and eructations having the taste of the oil have ceased, the quantity should be rapidly increased to one or two tablespoonfuls three times daily. Children rarely require more than a dessertspoonful. As the alkaline intestinal juices are most abundantly secreted after meals, the oil should be taken a little while after eating. As a rule, the various means used to disguise its taste, except perhaps alcoholics, soon become repulsive. Children, and many adults, soon become accustomed to its taste, and often take it with a relish.

Lipanin.—This term has recently been applied by J. von Mering, of Strasburg (see *Therapeutische Monatshefte*, Bd. ii., p. 49), to a substitute for cod-liver oil, consisting of pure olive oil and six per cent. of oleic acid. Like cod-liver oil, it speedily emulsifies in weak solutions of soda. It has an agreeable taste, and hence is readily taken even by fastidious patients. In numerous cases it was found to agree well with the stomach, even during the summer months, and in no instance did it cause nausea, vomiting, or diarrhœa. Given to adults in doses of from two to six tablespoonfuls daily, it notably increased the general strength and the body weight. J. von Mering concluded, after observing its action in numerous patients, that it is well adapted to all affections in which cod-liver oil is successfully used, and especially to cases in which a deficiency of pancreatic juice and bile in the small intestine renders the absorption of ordinary fats difficult or impossible.

Probably other oils, to which oleic acid has been added, such as cotton-seed oil, will be found to be equally digestible and useful.

Arsenic.—Arsenious acid and Fowler's solution, given in minute doses in cases of impaired general nutrition, slowly increase the body weight and the power of all the functions. Under their prolonged use, diseases due to malnutrition, especially those of the skin, nervous system, lungs, and stomach, generally improve, and sometimes completely subside.

Even in the healthy state of the body, arsenic may increase nutrition. Thus Kopp, who had been experimenting with arsenic and could not entirely prevent its access to his organism, in two months gained twenty pounds in weight. It is now well established that in Styria some peasants have the habit of consuming arsenic at regular intervals for the purpose of increasing their powers of endurance. In numerous careful experiments upon animals, Gies (*Arch. f. exper. Path u. Pharm.*, Bd. viii., p. 175) found that arsenious acid greatly promoted nutrition and decidedly increased the weight of the animals, and especially hastened the growth of osseous tissue.

In doses but little larger than those which promote nutrition, arsenic may cause incipient symptoms of poisoning—thirst, nausea, pain in the epigastrium, headache, sleeplessness, fever, conjunctivitis, and œdema of the eyelids. Usually these symptoms quickly subside when the use of arsenic is discontinued.

Arsenic is employed in numerous diseases due to malnutrition—the early stage of phthisis, chronic diseases of the skin, irritability of the stomach from catarrh, ulcer, or cancer, chorea, and in various forms of neuralgia. In malarial affections it is often used successfully, even when quinine fails, especially in the anomalous forms known as masked ague. According to late reports, it has proved more useful in idiopathic or pernicious anæmia than iron, cod-liver oil, and other remedies which augment the number of red blood corpuscles.

As a rule, the dose of arsenious acid should at first be minute; if necessary it may be gradually increased until the pathological condition for which it is given has improved, or until the incipient symptoms of its poisonous action become manifest. As soon as any of these take place, especially gastric irritation or conjunctivitis, the dose should be diminished or discontinued. In some cases, especially diseases of the skin, small doses should be given for some time after the symptoms of disease have disappeared, in order to prevent their recurrence. The minute dose of one-fiftieth grain of arsenious acid, or two drops of Fowler's solution, given after each meal, will usually produce a notable effect upon the general nutrition in one or two months. Prudence requires that Fowler's solution be ordered in a dilute form. ℞ Liq. potassii arsen., ʒ ss.; aq. menth. pip., aq. destil., āā ℥ i. M. Sig.: A teaspoonful after meals. ℞ Liq. potassii arsen., ʒ ss.; tinct. gentian. comp., ℥ iss.; syr. aurant., ℥ ss. M. Sig.: A teaspoonful after meals.

Phosphorus.—In minute doses phosphorus markedly promotes the growth of osseous tissue. In larger doses it augments the interstitial tissue of the stomach and liver, and induces chronic inflammation of these organs with atrophy of the secreting cells. Poisonous doses rapidly cause fatty degeneration of the stomach, pancreas, liver, kidneys, heart, muscles, and blood-vessels. As it forms a chemical component of nervous tissue, it has been supposed to be specially useful as a nutrient for the nervous system; but nothing indicating such action has been observed after the prolonged administration of minute doses, except that functional nervous diseases sometimes improve during its use.

Phosphorus is indicated in diseases of the bones requiring a more rapid or perfect growth of osseous tissue, such as osteomalacia, rickets, and insufficient ossification after fractures. It has been recommended also in various diseases of the nervous system, and seems sometimes to have been successful in those of a functional nature, such as neuralgia, nervous debility, incipient dementia, and impotence. It has been used with alleged success in obstinate skin diseases, and in leucocythæmia.

The dose of phosphorus ranges from gr. $\frac{1}{150}$ to gr. $\frac{1}{12}$. In rickets a daily dose of gr. $\frac{1}{120}$ was found sufficient. In neuralgia and other functional diseases of the nervous system, some practitioners have succeeded with doses of gr. $\frac{1}{100}$ to gr. $\frac{1}{50}$ given thrice daily. As much as gr. $\frac{1}{12}$ every four hours for twenty-four hours has been given in severe neuralgia.

The official *phosphorated oil*, containing one per cent. of phosphorus, and the *pills of phosphorus*, each containing gr. $\frac{1}{100}$, are convenient forms for administration. ℞ Olei phosphorati, ♏ xvi.–xxxvi.; mist. amygdalæ, ℥ ij.; ol. gaultheriæ, gtt. viij. M. Sig.: A teaspoonful one hour after meals.

Phosphide of zinc contains one-fourth its weight of phosphorus and is given in pill, in doses of gr. $\frac{1}{20}$ to gr. $\frac{1}{4}$.

Mercury.—Until recently it was supposed that mercury in minute as well as in large doses, given for some time, always exerts a deleterious influence on the general nutrition. In 1869 Liègeois reported that he had observed that subcutaneous injections of minute doses of corrosive sublimate had increased the body weight of healthy men. Bennet (1874) found that small doses increased the weight of dogs. Keyes (1876) carefully investigated the effect of small doses of mercury upon the red blood corpuscles and the general nutrition, and concluded that mercury acts as a tonic upon persons in fair health and not syphilitic, increasing the number of red blood corpuscles and the body weight. Schlesinger (1881), who made numerous careful experiments upon rabbits and dogs, fully confirmed the facts found by the above-mentioned observers.

Although no physician will be inclined to use mercury as a tonic in ordinary forms of emaciation and debility, yet it seems rational to employ it when the low state of nutrition occurs in persons who present symptoms of syphilis. According to Keyes ("Venereal Diseases," p. 119, New York, 1880), tonic doses may be continued steadily during several years without injury to the patient.

Samuel Nickles.

TONSILS, THE.—(Faucial tonsils. Amygdalæ. Tonsillæ.) (Tonsils of Luschka. Lymphoid or adenoid tissue at vault of pharynx.) (Tonsils of the Tongue. Lymphoid tissue at base of tongue.)

These organs are essentially collections of lymphoid tissue, differing in location and somewhat in appearance and function, but composed largely of the same elements. They are so situated as to form an interrupted circle extending completely around the pharynx. In the normal condition their presence is hardly perceptible.

Pathologically, while each may be affected by diseases peculiar to itself, there are many conditions from which all may suffer alike, since their histological structure is identical. It will be convenient, therefore, to study in one of them the minute anatomy and the pathological conditions common to them all, thus avoiding unnecessary repetition. The one most available for this purpose is the faucial tonsil.

I. FAUCIAL TONSILS.

General Anatomy.—The faucial tonsils are two glandular organs situated one on each side of the fauces, and between the anterior and posterior pillars of the soft palate. They consist essentially of reduplications, more or less extensive, of the oral mucous membrane, in which are enclosed an abundant deposit of adenoid or lymphoid elements, the whole organ having an identity and a special function of its own. The gross structure of the tonsil varies. Its usual shape is ovoid, and it more or less completely fills the triangular space between the anterior and posterior pillars of the palate. Its base is generally defined clearly, and corresponds with the greatest antero-posterior diameter of the tonsil. Its average vertical diameter is 20 mm., and its transverse diameter is 13 mm. Often a collection of lymphoid tissue lies below the tonsil, and sometimes above it, large enough to look like a small additional tonsil. Sometimes it extends as a narrow but slightly elevated strip far lower down in the pharynx than the usual limit. The gland is sometimes divided by a deep sulcus running across its antero-posterior diameter, generally above the centre, and thus separating it apparently into two distinct lobes. A supernumerary tonsil, the *tonsilla accessoria*, has been described.

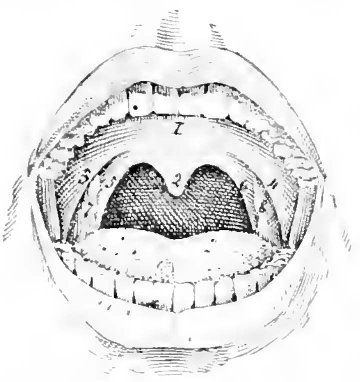

Fig. 4729.—The Tonsils. 1, Hard palate; 2, uvula; 3, 4, anterior pillars; 5, 6, posterior pillars; 7, 8, tonsils.

In early infancy it is sometimes impossible to demonstrate the presence of the tonsil, or, in fact, of the lymphoid ring, at all, while in other cases all of the elements of the latter have been found in a condition of marked hypertrophy soon after birth. Its period of greatest activity is just before puberty. It tends to atrophy with old age.

The surface of the tonsil is perforated by a varying number of depressions, slit-like or circular, the common orifices of the system of cavities which it contains. If the tonsil of the rabbit be considered as a single lingual follicular gland, we have in man a multiplication of this to the number of from eight to eighteen, the interval between any two adjacent glands forming a lacuna tonsillaris, crypt, or one of the system of cavities mentioned above. Many of them are spacious in extent, and they often penetrate deeply into the substance of the gland, sometimes almost reaching to its hilum. Often there are found in the interior of the tonsil single larger cavities, each of which includes several follicular folds and secures their common discharge at the periphery. The crypts of largest size and greatest depth are, as a rule, found in the middle part of the tonsil. By reason of this arrangement of the crypts the surface of the tonsil is thrown into numerous and extensive folds, and an extraordinary increase in the superficial extent of the gland is obtained. The crypts generally are filled more or less with a yellowish substance, composed of fat molecules, loosened pavement epithelium, lymph corpuscles, small molecular granules, and cholesterin crystals. Opening into the supratonsillar fossa, the triangular space at the top of the tonsil, are often numerous crypts, sometimes of large size. They are apt to be the exciting cause of acute or chronic inflammatory conditions of the tonsils, or of the parts in their vicinity, and they constitute an important feature of the anatomy of the part. In all examinations of the pharynx the supratonsillar fossa should be carefully studied.

In its minute anatomy the tonsil is for the most part like other so-called lymphoid glands. In common with the rest of the oral cavity it is invested with a thick covering of pavement epithelium. Proceeding from without inward, the surface epithelium is scaly, each cell having a flattened, circular nucleus. Beneath this the cells and their nuclei become less flattened. Still lower are found several layers of polyhedral cells, which have spherical nuclei and are connected together by intercellular cement substance. Among them are a certain number of prickle cells. The whole rests upon a single layer of columnar epithelial cells with oval nuclei, and is furnished abundantly with simple papillæ. Under the epithelium is a delicate endothelioid basement membrane. Following this is a tolerably compact mucosa formed of interlacing bands of fibrous connective tissue and containing many connective-tissue corpuscles. In the normal adult tonsil this structure is so delicate that sometimes it is hardly recognizable. In chronic disease of the gland it may become enormously increased. From it bands of connective tissue extend centrally into the larger tonsillary folds, and the whole forms essentially both an enclosure and a framework for the adenoid tissue or proper substance of the gland, as well as a nidus for its vessels.

The lymphoid tissue consists of a dense meshwork of fine, homogeneous fibrils which contains, besides occasional endothelioid connective-tissue cells, a large number of lymph corpuscles. These are small, round cells, each of which has a distinct spherical nucleus surrounded by a very thin covering of cell protoplasm. Near the cortex the lymph corpuscles are collected by means of delicate septa given off from the inner stratum of the capsule into a single row of oval masses called lymph follicles. Throughout the rest of the gland the lymph cells are diffused without any particular arrangement. Occasionally they extend so near the periphery as to penetrate the mucosa and encroach upon the epithelial layers. This is particularly the case in the interior of the crypts, where the epithelial layer is, as a rule, either wanting altogether or to be found only in occasional patches and in modified form, and where its thickness tends to decrease as the bottom of the lacuna is approached. In other words, the epithelial and subepithelial layers, thick at the periphery, become rapidly more delicate the deeper we trace them down the crypt wall, until, toward the lowest depth of the lacuna, they generally disappear. The tonsil is supplied abundantly with racemose mucous glands.

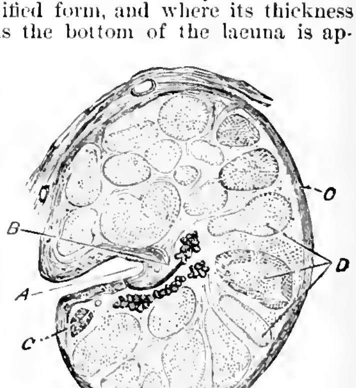

Fig. 4730.—Section of Normal Tonsil. (Morell Mackenzie.) *A*, Hilum; *B*, mucous gland; *C*, epithelial covering; *D*, lymphatic follicles; *E*, stroma.

The arteries which supply the tonsil are larger and more abundant toward its lower part. They accompany the connective-tissue sheath and its septa, give off a branch to each follicle and to the papillæ of the mucous membrane, and divide into a network of capillaries which unite to form one or more veins.

A lymph sinus, in open connection with a network of lymphatic vessels of the neighboring tissue, surrounds each follicle over more or less of its circumference, and sends prolongations outward.

The minute distribution of the nerves is not definitely known. Fibres from the sympathetic undoubtedly are supplied to the tonsil.

From its peculiar position with regard to important adjacent parts, and by reason of the frequency with which operative interference is called for in the treatment of pathological conditions to which it is liable, the surgical anatomy of the faucial tonsil is of the utmost interest.

The average interval between the free borders of both tonsils has been estimated to be 2.5 cm. (1 inch), so that, when the mouth is closed, the inner aspect of the tonsil touches the tongue.

In cases of normal size the tonsil extends but slightly, if at all, beyond the anterior palatine arch, which is formed by a projection of the palato-glossus muscle, and not at all beyond the posterior pillar, formed by the palato-pharyngeus. With both of these muscles it has fibrous attachments. A loose submucous cellular tissue extends from the anterior and posterior palatine arches toward the pharyngeal side of the tonsil, which facilitates infiltrations and the formation of abscesses, particularly in the anterior arch. Small bundles of muscular fibres, apparently independent, are to be found in the connective tissue of the external side of the tonsil which corresponds with the hilum. This side is also surrounded by fibres from the superior constrictor of the pharynx. Its outer aspect, moreover, is directed toward the internal pterygoid, from which it is separated by the above-mentioned muscular fibres, by the bucco-pharyngeal fascia, and by a thin layer of fat.

The relations of the tonsil with the internal carotid artery are not so intimate as is commonly supposed. Both carotids are behind it, the internal carotid a little over half an inch and the external carotid three-quarters of an inch distant from its lateral edge. The supply of blood conveyed to the tonsils is, if the size of these bodies be considered, remarkably large. They are nourished by the tonsillar and palatine branches of the facial artery, and by branches from the descending palatine, and from the ascending pharyngeal and dorsalis linguæ.

The ascending pharyngeal is often anomalous, for it not only varies greatly in its place of origin from the carotid, springing occasionally from the occipital or the internal carotid, and now and then being double; but also that branch which is distributed to the pharynx is often much larger than normal when the ascending palatine branch of the facial artery is unusually small. Cases are not infrequently observed in which the pulsations of the artery, enlarged as above stated, are plainly visible upon inspection of the pharynx. The vessel seems, generally, to lie directly behind the tonsil, and to be of considerable size.

Physiology.—The physiological function of the tonsil has never been established. From the experiments of Goodale and others it would seem that one of its offices is the arrest and destruction of pathogenic micro-organisms, although the extent to which it is capable of this is limited, and when the limit is exceeded, the tonsil becomes a potent carrier of infection.

Acute Inflammation.—*Tonsillitis.*—In the tonsil, as in other parts of the body, the general term inflammation includes a great variety of affections. Not only do we find in this organ the ordinary inflammatory conditions, general and specific, which may attack its various structures, but besides these there may occur special affections not commonly met with in other parts. The study, therefore, of the inflammations of the tonsil becomes a matter of unusual interest.

Acute inflammations of the tonsil are undoubtedly due to the influence of various micro organisms. In a certain number of cases the Klebs-Loeffler bacillus is found, although the clinical signs of diphtheria may be absent. More commonly are found the streptococcus, the staphylococcus, the diplococcus, the tetracoccus, and sometimes the pneumococcus. The presence of the Klebs-Loeffler bacillus does not seem necessary to render the disease infectious, and even when it is absent the risk of infection to other persons is to be considered. When paralysis follows tonsillitis, it is probable that diphtheria bacilli were present.

While acute inflammations of the gland in general possess characteristics of greater or less similarity the one to the other, the symptoms being quite uniform, it is nevertheless important to understand what symptoms are common to all cases, and what indications they offer for treatment, and also to appreciate the special conditions and needs which may exist in a given case.

Owing to the similarity in structure of the different parts of the lymphoid ring the inflammations which may affect them are practically the same. The conditions which are present in tonsillar inflammation, therefore, will well describe them all.

In general proliferative tonsillitis the follicles become enlarged through increase in the number of their lymphoid cells, particularly in the direction of the nearest crypt, and of the endothelial cells of the reticulum. According to Goodale, the proliferation of these endothelial cells gives rise to large phagocytic epithelioid cells that are characterized by a relatively large amount of markedly acidophilic cytoplasm, and an irregular, lightly staining, eccentrically situated nucleus. They contain in their interior from one to ten or fifteen cell fragments, which are generally lymphoid cells or red blood corpuscles in various stages of digestion. The lymphoid cells between the follicles are increased in number and closely packed together. The blood-vessels are dilated, filled with red and white blood corpuscles, and show more or less marked proliferation and exfoliation of their endothelial cells.

The epithelium of the crypts is diminished in bulk, from a widening of the intercellular spaces, which are crowded with escaping lymphoid and plasma cells. Bacteria, chiefly cocci, occur superficially in the epithelial lining of the crypts, but apparently they are absent in the lymphoid tissue. The crypts are filled with exfoliated epithelial cells, leucocytes, bacteria, amorphous débris, and in severe cases fibrin, which encloses cells and bacteria in a delicate network. At times the fibrin may extend from the crypts into and even beyond the epithelium, penetrating most deeply in the interfollicular region. Bacteria are most abundant near the surface of the crypt, gradually diminishing in numbers toward the base.

Suppurations below the mucous membrane may be local or diffuse. In some cases of tonsillitis abscesses form in the interior of the follicles, and finally discharge into the crypts. They have been found particularly in association with the streptococcus pyogenes. The growth of the abscess is usually in the direction of the nearest crypt. Sometimes peritonsillar inflammation is the result of the discharge of the intratonsillar abscess into the efferent lymph channels.

In diphtheria a diffuse necrosis of the epithelium may occur, or there may be a necrosis or ulceration extending into the lymphoid tissue from the crypts. Tuberculosis may affect all the parts of the ring, as may syphilis and mycosis.

Pathology.—Chronic enlargement of the tonsils is a true hypertrophy or hyperplasia, in which, according to Virchow, there is not only increase in volume of the gland, but an actual multiplication of all of its constituent parts. The epithelium covering the tonsil usually shows little change, but the papillæ underneath are often more numerous and less elevated than in the normal state; while, in the crypts, there seems to be a tendency for the membrane to become thinner as the bottom of the crypt is approached.

The substance of the gland may show one of two varieties of alteration. Either the lymphoid elements alone may be increased in amount, the stroma of the gland being little affected, or the fibrous tissue which constitutes the stroma may be greatly in excess of the normal degree. In the latter condition the lymphoid elements may be in excess, for a condition of general atrophy may be present. The external appearance of the tonsil in the first-named variety of disease is quite characteristic, the surface being rough and irregular in outline, dark red in color, and the substance of the gland being soft and compressible. The mouths of the crypts are usually more or less open, and the whole organ is deeply congested. Microscopical examination shows that while the lymphatic follicles are increased in number and size, the stroma is not markedly augmented. Such a tonsil may be removed easily, and, as a rule, without pain. In the other variety the surface is smooth and often glazed, the color is pink or even dull gray, the consistence firm and unyielding; while the mouths of the crypts are apt to be partly occluded, and the crypts themselves filled with broken-down excreta. Microscopically, the most striking feature of the section will be the remarkable proliferation of the fibrous stroma, which may be found more or less thickened at the periphery, and in the interior of the gland may be so greatly increased in amount as to encroach extensively upon the adenoid elements. In performing tonsillotomy in such a case great resistance to the knife or the tonsillotome may be experienced, and considerable pain caused by its passage through the tonsil. Again, the main blood-vessels ramify in the stroma. When the latter is normal or not excessive in amount, the walls of the vessels, when divided, easily close and bleeding is stopped. In fibrous tonsils, however, the excess of connective tissue surrounding the blood-vessels makes it difficult for the latter to undergo the normal process of retraction when divided, so that bleeding after the removal of such a tonsil is apt to be more prolonged than in the case of the first-mentioned variety.

The fibrous form is found during childhood, but is more common in adult life. Hence the greater liability of the adult to hemorrhage after tonsillotomy, the rule being that, in patients under twenty years of age, the operation is almost absolutely devoid of danger.

Etiology.—The causes of tonsillitis may be both predisposing and exciting. Of the former the most important factor seems to be youth, since it is most prevalent between the ages of fifteen and twenty-five years. It is rare in early childhood and after fifty, although a case is recorded in which suppurative tonsillitis took place in a child of only seven months. In many cases the tendency to tonsillar inflammations seems to be directly hereditary, and not referable to any mediate condition. Climate may play an important part.

Hypertrophy of the tonsils greatly increases the liability of the individual to acute attacks of tonsillitis. Sometimes this seems to be due to the retention, in the enlarged lacunæ, of excretory matter, which acts septically and so excites the adjacent tissue that a tonsillitis supervenes. Again, the tonsil seems, in many cases, to be a vulnerable spot, which is apt to sympathize with various irregularities of the body, and to be subject to inflammation as the result of dyspepsia, menstrual irregularities, rheumatism, and gout. A general condition of ill health may predispose to tonsillitis, and it is a matter of common observation that it may be caused by mental depression and by unusual anxiety or care.

The exciting causes of tonsillitis are usually ascribed to exposure to wet and cold. Septic influences, however, play an important part in their production.

In the latitude of New York tonsillitis is most frequent in the spring, next most frequent in the winter, less so in the fall, and least prevalent in the summer. It is most frequent in March, and least frequent in September. The disease is uncommon in tropical and in very cold climates.

Tonsillitis may be present as a complication in scarlet fever, measles, and smallpox. It may also be caused by the inhalation of irritating vapors or the swallowing of caustic substances. Finally, it may arise from various traumatisms, such as wounds, laceration from or impaction of foreign bodies in swallowing, and from the irritation due to accretions in the tonsillar crypts.

Classification.—Tonsillitis may be divided into several varieties, a convenient classification being as follows:

1. Superficial or lacunar tonsillitis, characterized by diffuse inflammation of the mucous membrane of the tonsil and accumulation of fibrinous exudation and desquamated epithelium in the crypts, which appears at the surface in patches of whitish exudation.
2. Parenchymatous tonsillitis, in which the deeper tissues of the tonsil are inflamed, and there is considerable swelling.
3. Croupous tonsillitis, in which a false membrane forms upon the tonsil.
4. Acute ulcerative tonsillitis.
5. Gangrenous or phlegmonous tonsillitis.
6. Peritonsillitis, with or without the formation of abscess.

Symptoms.—The symptoms which usher in an attack of tonsillitis are, in general, much the same for all varieties of the disease. In fact, it is often impossible for the physician, or even for the experienced patient, to predict, at the outset, the probable course of the illness.

In lacunar tonsillitis, supposing the case to be one of simple catarrhal inflammation, and not diphtheritic, the swelling of the tonsil is less considerable than in the suppurative form, but the mucous membrane is of a bright red color, and a whitish exudation is seen issuing from the mouths of the lacunæ, giving to the surface of the tonsil the appearance of being covered with a number of small, rounded patches.

Sometimes the deposit extends beyond the mouth of the crypt, and, this happening in the case of two or more lacunæ, the surface of the tonsil may present a considerable area of exudation from the coalescence of several individual patches. Follicular tonsillitis usually undergoes spontaneous resolution in from two to five days.

Another variety of tonsillitis is that in which there is observed upon the surface of the gland a distinct herpetic eruption, the mucous membrane and the parenchyma at the same time being violently inflamed. This condition generally runs the course of a simple acute tonsillitis, subsiding in two or three days. It is often associated with the earlier symptoms of some more serious affection, and particularly with those of pneumonia.

Acute ulcerative tonsillitis is sometimes seen in persons who have been exposed to debilitating influences, and who are at the same time surrounded by bad hygienic conditions. It is characterized by the appearance upon the tonsil of a deep, unhealthy, more or less extensive sloughing ulcer, which gives rise to much local pain and profound general disturbance. Its course is slow, and convalescence may be attended with much prostration.

Gangrenous or phlegmonous tonsillitis includes erysipelas and acute inflammatory œdema, grave conditions due to infection and described in Vol. VI, under the heading, *Pharynx, Diseases of: Acute Phlegmonous Pharyngitis.*

Peritonsillitis may end in resolution or in abscess. While abscess of the tonsil itself may occur, the pus generally discharging through one of the crypts, it is common for the abscess to be located outside of the tonsil, in the loose connective tissue upon which the latter rests.

Obstinate constipation almost invariably precedes and accompanies tonsillitis. The urine is highly colored, loaded with urates, contains an excess of urea, and is deficient in chlorides; albumin is sometimes found. The existence of albumin in the urine seems to be indirectly dependent upon the height of the temperature. When this is over 103° F., a trace of albumin is often present; but there are no casts, and the albumin generally disappears when the temperature begins to fall. Its presence is of no more importance than the transient albuminuria of pneumonia and erysipelas, although upon first finding it one is apt to feel uncertain as to whether the affection of the throat may not be diphtheritic.

In many cases of true-suppurative tonsillitis there is from the first a sensation of deep-seated pain and throbbing, which to the experienced sufferer marks the attack as one of quinsy. The general symptoms are malaise, chilliness, and febrile temperature, more or less pronounced, together with a sense of stiffness and dryness of the throat, and more or less pain in deglutition. As the soreness of the throat becomes worse the temperature tends to rise, until it may reach as high as 106° F. It is apt to rise most rapidly and to the highest point in the young, and, in the follicular form of the disease, may attain a maximum in a comparatively short time. Generally, however, the constitutional symptoms are more marked in the suppurative form. In patients of debilitated constitution the fever may assume almost a typhoid character, while the tonsils become dotted with a grayish exudation or are actually covered with sloughing, unhealthy ulcerations. In some instances the disease seems epidemic, attacking several persons in the same household and constituting the so-called "spreading quinsy," a disease suggestive of septic infection, and rarely observed without the coexistence of a definite source of infection. The progress of the disease may be unfavorable, leading to a true phlegmonous condition closely allied to genuine erysipelas, if not identical with it, and to extensive infiltration of the tissues of the neck in the vicinity of the tonsil, which has been known to extend downward as far as the clavicle; while the violence of the inflammation not infrequently produces an œdematous condition of the throat, which is occasionally fatal. The inflammation usually extends to the mucous membrane lining the Eustachian tube, causing decided temporary loss of hearing, and sometimes inflammation of the middle ear. Dysphagia in a severe case of quinsy is often intense, the patient being unable to swallow even his own saliva, and absolutely refusing to take food, because of the inordinate pain caused by every attempt at deglutition, and because, from the tumefied state of the parts, the stiffening of the muscles, and the general local disability, the act of swallowing is a physical impossibility. The patient may be unable to move the jaw, the mouth becomes covered with a thick yellowish-gray deposit, the breath is fetid, the teeth are covered with sordes, and the countenance presents an expression of great anxiety and suffering, characteristic of the disease. The location of the abscess may be either in the parenchyma of the tonsil or in the layers of connective tissue which lie between it and the outside of the pharynx. In the former case death has more than once been produced by the sudden rupture of the abscess during sleep, and the consequent strangling of the patient. When the abscess is peritonsillar this danger is also present. Instances are recorded in which, through the presence of a peritonsillar abscess, the walls of the internal carotid have become eroded, and rupture, with speedy death, has taken place.

Differential Diagnosis.—The diseases which may be mistaken for tonsillitis are diphtheria, phlegmonous pharyngitis, retropharyngeal abscess, scarlatina—when the rash is not well developed,—syphilis, cancer, and pharyngo-tonsillar mycosis.

In suppurative tonsillitis, the inability to separate the jaws, the fetid breath, the coated tongue, and the peculiarly anxious and suffering expression of the countenance, together with the comparatively slight systemic disturbance which often accompanies its earlier stages, are fair evidence of its nature. Examination of the tonsil by palpation will often be of material assistance; the organ feels hard and prominent, while the slightest pressure upon it gives rise to intense pain. By means of the finger the presence of pus may be demonstrated, the tissues having a characteristically doughy feeling, or else actually presenting fluctuation. In cases in which pus is suspected, but in which fluctuation is not apparent, Stoerk has suggested that, while the exploration of the tonsil is being made with one hand, the gland be supported from the outside by pressing gently with the other hand, behind and below the ramus of the jaw.

It is in follicular tonsillitis that the greatest difficulties of diagnosis will present themselves, the desideratum being to distinguish the simple forms of that disease from true diphtheria. While simple follicular tonsillitis is generally distinguished from diphtheria by the absence of glandular swelling of the neck, albuminuria, and subsequent paresis of the pharynx, nevertheless, all of these symptoms may be present. The nature of the exudation also may be misleading. Usually the catarrhal exudate is confined to the mouths of the crypts, and may be easily stripped from the surface of the mucous membrane and dragged from the crypts, leaving the subjacent membrane intact; while in diphtheria the membrane is deposited in patches upon the surface of the gland, is adherent, and, when torn from its place, leaves the membrane underneath distinctly eroded and bleeding. Nevertheless, these differences are not always to be depended upon. The relative height of the temperature and the quality of the pulse are important diagnostic signs. In follicular tonsillitis the temperature is usually high, rarely under 102° F. and occasionally as high as 106° F., rising suddenly and, in many cases, falling with almost equal rapidity. In diphtheria it seldom rises above 102° F., gradually attaining that point, and remaining in its neighborhood for a considerable length of time. In follicular tonsillitis the pulse, although perhaps rapid, is usually full, bounding, and regular. In diphtheria it is rapid, markedly depressed, and sometimes irregular.

If albumin be found for the first time on the second or third day, the temperature being at 103° F. or more, and if it disappear on the fourth, we are almost surely dealing with a case of simple tonsillitis. The diagnosis will, of course, be rendered more simple if a history of exposure to the diphtheritic poison can be obtained, or if the Klebs-Loeffler bacillus can be demonstrated.

Tonsillitis may be differentiated from the sore throat of scarlet fever by the absence of the characteristic exanthem and of the symptoms of the latter disease usually seen upon the tongue and pharynx. It must be remembered, however, that in true tonsillitis there is, rarely, a slight skin eruption.

Syphilis may be differentiated from tonsillitis by the symmetry of its manifestations and by the presence of ulceration, the latter being an unusual condition excepting in the former disease.

On several occasions the writer has seen primary cancer of the tonsil mistaken for quinsy. The gradual development of the former and its duration, extending over a period of weeks or months, will exclude tonsillitis, while the facts that cancerous disease is unilateral, that it almost invariably occurs in patients over forty years of age, and that it is unattended with febrile symptoms, point clearly to the true nature of the affection.

Duration.—The duration of an attack of simple parenchymatous tonsillitis is generally from three days to a week. In follicular tonsillitis the disease may run its course in a surprisingly short time. From two to five days would be a fair estimate of its average length. In quinsy the probable duration is most uncertain, and there is in many cases a tendency to relapse; or, the process having been completed on one side, the opposite tonsil may become affected, and the whole tedious history of suppuration be repeated. Thus, the time required may extend over several weeks.

Prognosis.—The prognosis in the milder forms of tonsillitis is almost invariably good, and the progress toward recovery often wonderfully rapid. This is by no means invariably the case. Follicular tonsillitis is often followed by marked debility, while an attack of suppurative tonsillitis may be succeeded, in persons of debilitated constitution, by a tedious convalescence and long-continued general depression. Moreover, one attack seems to predispose to others, and with some patients every year brings with almost certain regularity one or more exacerbations. Death from quinsy has been known to occur in one of three ways: By sudden rupture of a large tonsillar abscess during sleep, resulting in suffocation; by the violence of the inflammation causing infiltration of the neighboring parts, which, extending to the larynx, produces œdema of the glottis; and by erosion of the walls of one of the large arteries adjacent to the tonsil, followed by fatal hemorrhage.

Treatment.—In all forms of tonsillitis the treatment, to be effective, must be both general and local.

General Treatment.—Rest in bed should be enforced. Since acute tonsillitis is almost invariably attended with constipation, the first and most important measure is the administration of an effective purgative. Attention to this feature must be paid throughout the course of the attack. This holds true for all varieties of the disease.

With regard to general therapeutic measures directed toward the disease itself, innumerable plans and drugs have been proposed. In almost every instance they have proved valueless. Some, however, have gained a fair reputation for usefulness. The effect of drugs upon tonsillitis varies greatly in different individuals. What may be almost a specific for one seems with another to be inert.

To be effective, general treatment must be instituted as soon as possible after the commencement of the attack. For a simple case in an adult the best plan is to administer, alternately, every fifteen minutes, half a drop of tincture of aconite (Fleming's) and half a drop of tincture of belladonna, watching carefully for indications of the physiological effects of the drugs and stopping the medicine upon their appearance. This method promises much better results than the administration of opium in the form of a ten-grain Dover's powder, or of a large dose of sulphate of quinine, although both of the latter are occasionally serviceable.

In the cases which seem to be of rheumatic origin three remedies have been highly recommended. These are salicylic acid, guaiacum, and the bicarbonate of soda. Of these the first is, in the experience of the writer, the most reliable. A convenient form for its administration is in capsules, each containing five grains of salicylate of soda, with a small quantity of quinine, generally about one grain, one such capsule to be taken every two, three, or four hours, as the case may require. The use of guaiacum has never been popular in this country, and at present is practically abandoned. The use of bicarbonate of soda, taken internally and also applied locally to the tonsil, has gained many supporters.

In all forms of tonsillitis iron is invaluable. While there are many preparations of greater elegance, none is so effective and reliable as the tincture of the chloride, which not only acts constitutionally, but, in the process of deglutition, is applied locally to the surface of the tonsil, where its antiseptic and astringent effects are most salutary. It may be administered most conveniently in glycerin, in the proportion of three parts of the latter to one of iron; from half a drachm to one drachm of the mixture to be given, as the case may require. The addition to the dose of the iron and glycerin mixture of about one ounce of cold Vichy water makes a decidedly palatable drink, and prevents the iron from staining the teeth. Quinine may also be given in tonic doses, and the nutrition of the patient must be carefully maintained. During convalescence the administration of bitter tonics and iron will materially hasten recovery.

Local Treatment.—The employment of well-selected local measures in the treatment of acute affections of the tonsils is of the utmost importance. It is not too much to say that there is no case of tonsillitis, whatever may be its nature or its degree of severity, which cannot be benefited, and the more distressing symptoms palliated, by means of applications made directly to the affected parts; and while the use of local applications cannot do away with the necessity for the constitutional treatment of the general condition underlying a given attack, the two should go hand-in-hand, each being essential to the successful working of the other.

Local applications may be made either to the neck, in the region of the tonsils, or directly to the glands themselves. If the onset of the attack be recognized at an early period in its history, much may be done to abort it by the use of cold applied to the neck over the region of the tonsils. The application may be made in one of several ways. The old-fashioned plan of dipping a folded handkerchief in cold water, wringing it out, and tying it over the neck in the neighborhood of the tonsils by two or three turns of a flannel bandage, is often productive of good results. Lennox Browne gives excellent directions for making a wet compress for the throat, and advises as follows: Take a piece of lint twice as large as may be required to cover the desired area—that is, from angle to angle of the jaw—or a piece of linen four times as large, the former to be folded twice, the latter four times. Saturate this with cold water, apply it over the region of the larynx (or tonsils), and cover it with a piece of oiled silk, rubber tissue, oiled paper, or other waterproof material, which must be at least half an inch larger than the compress in every direction. By lining the oiled silk with flannel, greater adaptability is obtained. Secure the compress by means of a handerkchief tied twice around the neck. Far more convenient is spongiopiline, as commonly made and sold in this country. By means of this most convenient dressing, applications of either heat or cold can be made, and with the least possible annoyance to all concerned.

In the later stages of suppurative tonsillitis, poultices of linseed meal or spongio-piline, are often of great benefit. The application to the throat of dry cold is a valuable therapeutic measure in a large variety of inflammatory conditions. The writer has employed it in certain cases by partly filling a small bladder with pounded ice and laying it over the neck so as to cover the space adjacent to the tonsils. Sitwell's improved surgical water bandage or temperature regulator, made of the best quality of soft india rubber, is extremely light in weight and elastic, and hence remarkably adaptable, convenient, and comfortable.

For outside application the use of pigments, counterirritants, and leeching is, as a rule, not to be recommended, since they are far more likely to increase than to diminish the discomfort of the patient. When required, a simple stimulating liniment of ammonia well answers the purpose, while the use of cold, as already described, early in the attack, or of warm poultices later, will be found both grateful to the patient and beneficial.

When excessive secretion is an annoying feature of the case, some advantage may be derived from the external application to the throat of belladonna liniment.

Internally, the use of inhalations of steam and of hot sprays has become unpopular. Much better is the following process: Let the patient lie upon his back, partly fill the mouth with hot water, turn the head until the face is uppermost, and thus allow the water to gravitate toward and upon the affected parts. This will succeed as well as any ordinary act of gargling, and with little or no discomfort. It may be repeated as often as necessary. It is generally productive of so much comfort that the patient soon realizes its value and will desire its repetition. This is true even of children. If desirable, the fluid may be medicated, the addition of a small proportion of bicarbonate of soda, or of borax, being especially helpful in facilitating the removal of the viscid secretions common in such cases.

An extensive area lies behind and above the tonsils, which may be more or less filled with irritating secretion, and which washes, applied as above, cannot reach. For cleansing these parts, no method is more satisfactory or more gentle than the careful injection of spray, through the anterior nares and backward into the pharynx. This may be done by the patient himself, or by an attendant, by means of any good hand-ball atomizer throwing a horizontal jet, and when properly employed it is capable of giving the greatest relief. The same spray may be used through the mouth, directly toward the tonsils and pharynx. The use of the post-nasal syringe in acute inflammations of the tonsils and pharynx is dangerous, and should never be allowed. Even the spray may enter the Eustachian tubes. In order to prevent this the patient should be directed to avoid blowing the nose, and always to draw the fluid from before backward and into the pharynx. While in chronic conditions harm has probably very seldom been done by the use of the spray, in acute cases it has been beyond question the cause of serious middle-ear inflammation. Applications of medicated fluid to the tonsils may be made to the best advantage with a hand-ball atomizer. One of the best applications in the early stages of tonsillitis is a saturated solution of the extract of suprarenal glands.

For purposes of cleansing and disinfection, an alkaline solution containing some good disinfectant will be most useful. Dobell's solution, if employed at all, should be largely diluted with water.

In suppurative tonsillitis, as in the formation of abscesses in other parts of the body, the most important consideration is the early recognition of the formation of pus and its speedy evacuation. A tonsillar abscess left to run its own course will, without doubt, and in due time, break. The question of surgical interference, however, must be considered, and for two reasons: First, because of the possibility of danger from the sudden rupture of a large abscess during sleep. Second, and far more important, because by a timely incision the abscess may be evacuated, the progress of the disease cut short, and the patient saved perhaps many days of extreme suffering and depression, and, possibly, the danger of blood-poisoning.

In the use of the knife in such cases, certain rules should be observed and precautions taken:

1. Scarification of the surface of an inflamed tonsil, while sometimes beneficial, is generally irritating, and not likely to afford more than a questionable amount of temporary relief.

2. In quinsy incision is indicated when, from the presence of distinct fluctuation, the spot at which the abscess is pointing may be evident; or, when the tissues are swollen and boggy, and there is reason to believe that pus may underlie them. The instrument most convenient for the purpose is a common scalpel, of medium size, the blade of which should be protected to within half an inch of the point, so that not more than the above amount of the cutting surface is exposed. In selecting the point at which incision should be made, it must be remembered that the abscess may be quite superficial and in the substance of the gland, or deep and involving more the connective tissue outside the tonsil. In the former case, it is best to enter the tonsil itself, making the incision horizontally and from without inward. When the abscess lies more to the outside of the tonsil, palpation of the gland may fail to demonstrate any sign of pointing. If, in such a case, the finger be applied to a point opposite the tonsil, outside of the anterior pillar of the velum, it will often be possible to detect distinct fluctuation; the space between the palato-glossus and the palato-pharyngeus muscles being covered simply with mucous membrane. If now the knife be entered at this point, and made to penetrate to only a moderate depth, pus may be found and the abscess opened, when incision of the tonsil itself would have failed.

In such a case the line of incison should be from above downward and slightly outward, following the direction of, and parallel with, the anterior pillar.

In cases in which the swelling of the tonsils is so great as to threaten suffocation, and in which simple incision does not seem sufficient to evacuate the abscess or reduce the tumefaction, one of two surgical procedures may be resorted to. Either the tonsil may be excised and its inflamed and swollen tissue removed, or tracheotomy may be performed. Intubation is, of course, inadmissible, since the obstruction is not in the larynx, but above and outside of it. The writer has seen two cases in which a timely tracheotomy would have saved the patient's life. On the other hand, when the tonsils themselves are enormously enlarged and the tissues around them not too greatly infiltrated, when the abscess is evidently in the substance of the gland or immediately in its vicinity, and when there is danger of septic infection, excision offers an effective, speedy, and tolerably safe means of relief. In acute exacerbations of tonsillitis, particularly in children whose tonsils are chronically hypertrophied, instances are not wanting in the experience of most specialists in which a tonsillotomy, promptly performed, has averted a dangerous issue.

3. When, as is often the case in chronic hypertrophy of the tonsil, the patient suffers from recurrent attacks of quinsy, excision of the tonsil is of the greatest value, and in many instances the operation will effect a radical cure. As a rule, tonsillotomy should not be performed while the gland is in a state of acute inflammation.

4. In some cases the tonsils are sufficiently enlarged to admit of excision only during an acute attack. In these it is better to operate at once, and at the beginning of the acute inflammation. Thus, the redundant tissue may be more thoroughly removed, the present attack cut short, and future trouble avoided. Pain is greater from such an operation, and hemorrhage is more likely to be active. Experience, however, proves its value.

Chronic Inflammation of the tonsils, although generally associated with more or less hypertrophy, is sometimes observed as a disease of the crypts of the gland, the so-called chronic lacunar tonsillitis—an annoying, and often an obstinate, condition of disease attended with inflammation, dilatation, and obstruction of these follicles. The crypts are often found to contain white or yellowish masses of cheesy detritus which have a particularly bad odor. The presence of these masses is very irritating to the patient. They are likely to cause more or less inflammation of the surrounding parts, sometimes to the extent of producing abscess. Many large crypts open into the supratonsillar fossa, and there is often a large and deep sulcus formed by adhesion of the anterior pillar of the velum to the tonsil. These cavities are particularly liable to become diseased. The treatment of this condition is simple and effective. It consists in the free opening of each crypt, from top to bottom, by means of a sharp, specially constructed knife, or by the galvano-cautery and the subsequent application of a strong solution of iodine to the walls of the crypt. Few operations are capable of giving more relief. The parts soon resume a healthy condition, and the symptoms, local and reflex, disappear.

Chronic Hypertrophy.—*Etiology.*—Hypertrophy of the tonsils is sometimes congenital. It is often noticed when the child is but a few months old. Sometimes it becomes developed about the age of puberty. In the experience of the writer, many cases owe their origin to diphtheria, an attack of which has left the throat inflamed and highly sensitive to irritating influences, in which state the tonsils become permanently enlarged or liable to recurrent attacks of acute inflammation, through which hypertrophy takes place. Scarlatina, measles, or whooping-cough may serve as a starting-point for it, and syphilis, congenital or acquired, and tuberculosis may also be its chief causes, while many cases seem to result from recurring attacks of quinsy. Often the condition appears to be excited by the irritating effects of acid indigestion.

It appears that the tendency to enlargement of the tonsils is in direct relation with the general activity of the gland, and that, active at birth, the susceptibility increases rapidly until at the time of puberty it is at its height. From this time there seems to be a decline, which becomes progressively rapid until, beyond thirty, the disease is more and more uncommon. While atrophy may and does occur at or about puberty in a few instances, in quite as many cases tonsils hitherto normal become enlarged; and hypertrophy may take place in them, not only at the time of puberty, but at any period within fifteen years or even more after the age of adolescence. If, therefore, it be true that even a healthy tonsil may become chronically hypertrophied after puberty, how much more probable is it that one already enlarged in childhood may continue in that condition.

Symptoms.—The symptoms of tonsillar hypertrophy are usually pronounced.

In a well-marked case the first signs to which attention will be called are those seen upon the countenance of the patient. The complexion is pale, cachectic, and transparent, the veins standing out in distinct relief; the lips are often dull pink, or even blue; the eyes are heavy and lifeless and their lids are drooping; the mouth is partly open, and often the upper teeth project forward. When the child is stripped his body is seen to be emaciated, and his muscles flabby, the intercostal spaces are retracted, and the breast bone is prominent.

These appearances are such as would arise from obstructed nasal respiration.

Voice.—Another mechanical effect is the alteration in the voice, which in such cases is generally thin, nasal, and lacking in resonance. The explanation of this lies in the fact that the pharynx and the air cavities above act, in the production of tone, as resonators. Obstruction of the pharynx directly prevents the proper formation of tone and thus impairs the quality of the voice. Again, the voice is injured by the effect of the lymphoid inflammation upon the soft palate, which in such cases is generally relaxed, and hence unable to fulfil its functions in a proper manner. In consequence of this, articulation is interfered with, the patient speaking with thick utterance, and the palatal consonants being in particular mispronounced. When we add to the above the injurious effects upon the laryngeal mucous membrane of the catarrhal inflammation often associated with, and aggravated by, chronic hypertrophy of the tonsils and pharyngeal adenoid tissue, the deleterious influence of this condition upon the voice may be fully appreciated.

Respiration.—Mouth-breathing is one of the commonest symptoms of naso-pharyngeal obstruction, and it is associated with a variety of evils. Moreover, the amount of air admitted to the lungs is often entirely insufficient. A patient suffering in this manner almost invariably gives a history of respiratory difficulty, particularly well marked during sleep, at which time the mouth is widely opened and respiration is noisy, and nearly always accompanied with loud snoring; sleep is restless and broken, the patient being feverish and tossing about and dreaming incessantly, often muttering or talking, and sometimes, it is said, indulging in somnambulism. In severe cases intense reflex phenomena manifest themselves, among which a not uncommon symptom is for the patient to be awakened by sudden attacks of

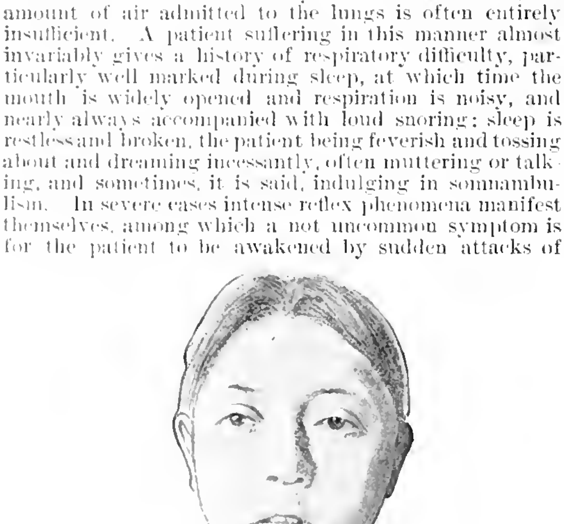

FIG. 4731.—Facial Expression Characteristic of Pharyngeal Adenoid Hypertrophy. (After Gerber.)

dyspnœa, so severe in some instances as to threaten suffocation, and attended with severe exhaustion and alarm.

The patient awakens after such a night feeling dull and tired, and often with a headache. The throat is dry and parched, the breath fetid, and the appetite impaired.

The respiratory function of the nose being abolished, the air in its passage to the lungs is neither moistened, nor warmed, nor freed from impurities. In consequence of this the respiratory passages are rendered abnormally dry, the lungs are subjected to the danger of irritation from cold, and the whole tract, from the naso-pharynx downward, is made liable to the effects of whatever foreign matters may be inhaled. The effect of obstruction to nasal respiration is such as to exert an important influence upon the nutrition and development of the nose itself. Without question, a proper supply of air and the normal exercise of the part are necessary for its proper and complete development. Hence, as long ago suggested by the writer, deformities of the bony structures of the nose, so commonly found in mouth-breathers, are caused by the effect of the mouth breathing upon the development of the nose, and that asymmetry of the nasal cavities, and indeed of the superior maxilla itself, may be due to the same influence when exerted unilaterally.

In many children in whom obstruction to breathing is serious, there will be noticed a marked effort on the part of the walls of the chest to complete the act of respiration, the intercostal and infraclavicular spaces sinking inward with each attempt. Under such circumstances serious changes in the thoracic parietes may take place.

Hearing.—The effects of nasal obstruction upon the hearing are highly injurious. They are exerted in two different ways, each of which is capable of producing marked results. The catarrhal inflammation commonly present in the pharynx of such a patient produces a general chronic swelling and congestion of its mucous membrane, with thickening and retraction of the drum membrane and loss of hearing. This same retraction of the drum head is caused in certain cases by the mouth-breathing habit, the upper pharynx not being properly supplied with air. This opinion is sustained by the fact that after removal of the obstruction the hearing distance is often greatly increased, and with as much promptness as it is after the use of the Politzer inflator. The danger to the auditory sense from hypertrophy of the lymphoid tissue, particularly that at the vault of the pharynx, is decided, and its importance cannot be overestimated. When, therefore, there is reason to suspect that deafness may be due to it, the necessity for the thorough investigation of the pharynx becomes strongly emphasized.

Smell and Taste.—Owing to the catarrhal inflammation present in lymphoid hypertrophy of the pharynx, the senses of smell and taste are often impaired or altogether lost. In the case of olfaction the diminished special sensibility is also due to the occlusion of the pharynx and to mouth-breathing, by reason of which the odoriferous particles are prevented from reaching the olfactory region. On the other hand, the constant presence of fetid discharges makes itself apparent to the patient himself and to those about him. With lymphoid hypertrophy there is generally associated much chronic catarrhal irritation of the neighboring mucous membrane. Removal of the hypertrophied tissues will be followed in most cases by marked amelioration of the catarrhal symptoms, the improvement commencing immediately after the operation and continuing more or less steadily for months.

In the diseased state of the pharynx, the secretion becomes greatly increased in amount, and it, together with the abundant supply of mucus given off by the neighboring membrane, is a source of much disturbance. Not only does the pharynx become filled with it, by which respiration is rendered more difficult, but when swallowed it is apt to give rise to indigestion. Again, through failure to enjoy it, the act of eating is accomplished rapidly, and the food is swallowed in large masses without having been properly masticated. Thus the nutrition of the patient is directly attacked; for, through loss of taste and smell, and through the depressing influences of a lack of oxygen, the appetite is generally impaired at the outset, while, by reason of the faulty mastication and of the dyspepsia, the food ingested is not properly utilized.

When it is remembered that loss of oxygen, loss of sleep, and loss of nourishment may all arise from the disease under consideration, its influence upon the general health cannot but be recognized.

Lymphoid hypertrophy may occasion various reflex nervous phenomena. Of these, the most important is the occurrence of attacks of dyspnœa, generally during sleep, which seem to be due to a veritable spasm of the glottis, and in the course of which the patient is awakened suddenly from a sound sleep to find himself choking. For a few seconds inspiration is almost impossible, and efforts to accomplish it are accompanied by loud, stridulous breathing, and intense apprehension and alarm. It may be urged that such accidents might arise from the presence of a deposit of thick, tenacious mucus in the larynx, and such, no doubt, is often the explanation of them. However, in certain instances, observed by the writer and others, there can be little doubt as to the spasm being of a purely neurotic nature.

Severe spasmodic cough is sometimes seen in children and in young adults. It is generally dry and hacking in character, and in some cases is almost incessant.

Again, chorea and even epilepsy are sometimes observed.

The influence of lymphoid hypertrophy upon the circulation is a matter of importance, deficient oxygenation of the blood not being the only result which may be traced to this condition in such cases. Anæmia is a common symptom, and one which is often particularly well marked. Some believe that enlargement of the heart by dilatation may be directly due to this impoverishment of the blood. Disturbed cerebral circulation, as a result of pressure exerted by the enlarged masses, has been suggested by Chassaignac.

Diagnosis.—The diagnosis in chronic hypertrophy of the faucial tonsils may usually be made with the greatest ease, the history of the patient, his general appearance, and his symptoms pointing almost invariably to the source of the trouble. Any doubt may be dispelled by the simple inspection of the pharynx. Upon opening the mouth and looking into the throat, the tonsils will appear extending beyond the normal limit and toward the median line, and their relative size, their consistence, and the condition of the crypts may be ascertained. During easy, deep inspiration the tonsils will assume their normal position behind the anterior pillar of the velum, a minimum of their volume being projected toward the median line. If now the patient be made to gag, the tonsils will be rotated forward and thus brought out from behind the velum and into plain view. Any doubt which may exist as to the real size of the gland may be removed by placing one forefinger just below the angle of the jaw externally, and the other behind the tonsil, when the whole extent of the enlargement may be recognized.

Prognosis.—Hypertrophy of the tonsils may exist to a considerable degree, both in children and in the adult, without giving rise to serious symptoms. In some cases the presence of this condition may pass unnoticed. Usually, however, the contrary is the case. It may be said, in general, that the younger the child the more injurious is the effect likely to be. While the tonsils may sometimes regain their normal condition at puberty, the occurrence of this atrophy is uncertain, as has already been pointed to in the section relating to the etiology of the disease. Meanwhile the general health of the patient may be undergoing serious injury, and irreparable damage may be inflicted upon adjacent parts. The prognosis, therefore, in pronounced cases of tonsillar enlargement is unfavorable as to the ultimate subsidence of the difficulty.

As to the effect of enlarged tonsils upon the life of the patient, there can be no question that they may be an indirect cause of death. The writer has seen a case in which, operation having been refused, death from asphyxia resulted in a child two and one-half years old, suffering from enormous hypertrophy of both tonsils. Such a thing, fortunately, is extremely rare; but it is worthy of record if for no other reason than to prove the possible danger of the condition, and to emphasize the folly of temporizing with it.

In cases of moderate hypertrophy of recent standing, in which there is little deposit of fibrous tissue, and in which the enlargement depends upon an increased vascularity and dilatation of the crypts, much good may be done by general and local hygienic measures and by local medication. Careful attention should be paid to the dietary, physical exercise, and general surroundings of the child, and any diathesis discoverable should be diligently treated.

In some cases the administration of the iodide of iron and of cod-liver oil will be found beneficial. Externally, a valuable measure is the habitual application, every morning, of a cold bath of salt water. This should be applied to the neck and throat by means of a sponge, the water being at a temperature sufficiently low to produce a reaction, but not so cold as to shock the patient. Meanwhile, the throat should be well rubbed, and special attention paid to the region over the tonsils, which, by a process of massage gently applied, may be successfully stimulated, and the blood-vessels caused to act with greater liveliness and tension. The application of massage directly to the tonsil has been recommended, but has not generally commended itself. The application, to the inflamed tonsil, of the constant galvanic current is a measure deserving of attention.

Local applications to the tonsil are usually ineffective, as are the measures suggested above. Sooner or later, in the great majority of cases, their futility will be recognized and surgical measures accepted.

Removal of the tonsils has been practised from earliest times. For its accomplishment several methods have been employed, some of which are still in vogue.

An exhaustive history of the subject is given by Sir Morell Mackenzie in his classical work.

In 1757 Caqué proved indisputably that the great dread of hemorrhage which had existed was chimerical, and that the resulting wound healed readily in a short time. From this date excision of the tonsils became one of the recognized operations of surgery.

The surgical treatment of this condition extends backward for many centuries. When we add to this the fact that the disease is common, and that it has been extensively studied in recent years, it will also appear that our present knowledge of the subject is based upon the views of a vast number of distinguished and highly experienced authorities. Of the methods for removing the tonsils most commonly used at the present time may be mentioned cauterization, by chemical or electrical escharotics; écrasement, by means of the galvano-caustic loop or of the cold wire; abscission, by means of some modification of the knife or scissors. Both the tying off of the tonsil by means of a ligature, and the injection into its substance of various supposed absorbents, only need be mentioned to be condemned. The practice of enucleating the tonsil with the finger has been lately revived in some quarters. It is of questionable value and propriety.

The use of the galvano-cautery, as advocated by Voltolini, has had many supporters. As compared with the knife or cold snare, however, the process is slow and painful, the reaction often severe, and the resulting cicatrices in no small number of cases a permanent source of irritation and disability. The method is distinctly inferior.

Écrasement by means of the galvano-caustic loop is sometimes an effective and valuable method, although in simple hypertrophy, uncomplicated with malignant disease, it will be found less convenient and far more painful than other methods. When this instrument is used two precautions are necessary: The electric current should be employed intermittingly, and traction should be made upon the loop only during the passage of the current. Thus hemorrhage may possibly be avoided and the danger of injury to the pillars of the fauces by diffusion of heat may be prevented. Any unevenness remaining may be removed by subsequent cauterizations. Inclusion of the greater part of the tonsil within the loop may usually be effected by dragging it inward by a forceps or by means of a transfixion needle. Local anæsthesia may sometimes be obtained by injecting into the parenchyma of the gland, before operation, six or eight minims of a four-per-cent. solution of cocaine. The amount of tissue actually removed by the snare does not represent the total effect of the operation, since the parts remaining are cauterized to a considerable depth.

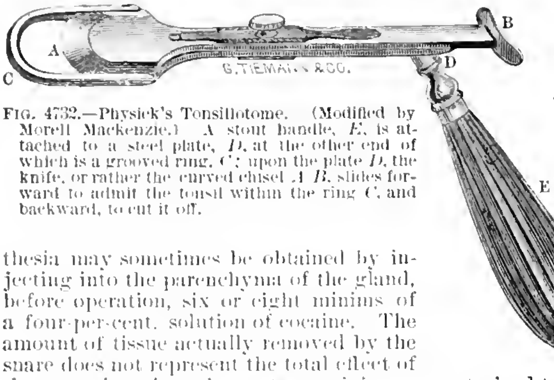

FIG. 4732.—Physick's Tonsillotome. (Modified by Morell Mackenzie.) A stout handle, *E*, is attached to a steel plate, *D*, at the other end of which is a grooved ring, *C*; upon the plate *D*, the knife, or rather the curved chisel *A B*, slides forward to admit the tonsil within the ring *C*, and backward, to cut it off.

In certain instances, in which the tonsil is very large and fibrous, and the patient an adult, it may be desirable to use the cold wire écraseur. The operation is tedious and in many cases extremely painful, and, unless it is performed while the patient is under the influence of an anæsthetic, it is not likely that it will be tolerated by any but a remarkably hardy individual. On the other hand, if it be performed under general anæsthesia—as, for example, in the course of an operation for the removal of adenoids and upon a tonsil which is fairly pedunculated—it is the best method at our command. More of the tonsil is removed, the resulting wound is much smaller, and the bleeding is reduced to a minimum. Healing is more rapid and is accompanied with considerably less pain.

Tonsillotomy.—Of all methods hitherto proposed for the removal of enlarged tonsils, none can compare in general popularity, utility, thoroughness, and, on the whole, humanity, with tonsillotomy. As time has gone by, the value of the procedure has become more and more completely established. Meanwhile the instruments for its performance have appeared in large numbers and in great variety.

In the Physick tonsillotome, as made after the pattern represented in Fig. 4732, a high degree of simplicity and perfection has been attained, and although many modifications of this instrument are offered for sale, it is safe to say that, up to the present time, it stands unrivalled.

It is the favorite tonsillotome of nearly every recognized authority. It is absolutely simple in construction, not liable to get out of order, comparatively easy to clean, and, what is far more important, it is a safe instrument to handle, the accidents to which the Fahnestock instrument (Fig. 4733) is liable being with it impossible. With it the danger of hemorrhage is reduced to a minimum.

For the convenient and successful performance of tonsillotomy the aid of a trained assistant is indispensable. With adults and with children old enough to be under good self-control, he will be of use in steadying the patient's head and in supporting the tonsils; while with young children the possibility of operating at all will sometimes depend upon the manner in which the patient is held.

During the operation the patient should sit facing a good light, the operator with his back to it. Those surgeons, however, who are familiar with the use of the head-mirror will generally prefer to use this instrument for illuminating the field of operation. The patient, if an adult, should sit upright and well back in the chair, the head fixed against a properly adjusted head-rest or supported by an assistant. The latter should stand directly behind the chair, and, while holding the head with both hands, should place the fingers of each hand over the tonsillar region of the corresponding side, that is, immediately below the angle of the jaw. Thus the tonsils may be prevented from receding before the pressure of the tonsillotome when it is introduced, and the operation may be performed with greater accuracy, and, if necessary, with greater thoroughness.

In the case of a child the assistant should be seated in front of the operator, and the patient seated across one of his thighs, facing inward, so that the legs of the latter may be grasped and firmly held between the thighs of the assistant. The body of the child is partly turned so that he faces the operator, and his head is rested against the breast or the shoulder of the assistant, who controls the arms and body of the child by throwing one of his arms across the patient's chest, while with the other hand he steadies the child's head firmly against his own body. The use of a mouth gag is unnecessary. The blade of the tonsillotome is now drawn backward and the instrument introduced flatwise and in the median line, as if it were a tongue depressor, as far back as the pharynx. It is then rotated, by raising the handle outward from the vertical to the horizontal position, until the plane of the blade becomes parallel with the plane of the desired incision. Following this comes one of the most important manœuvres of the whole operation, and one to which too much attention cannot be paid, namely, the engaging of the tonsil in the ring of the instrument. In carrying the tonsillotome outward from the median line, the tendency is for the handle of the instrument to be carried out too rapidly. In other words, the angle of the mouth is used as a fulcrum against which the middle of the instrument rests, and while the handle is carried outward the other end is carried in the opposite direction, or inward, and away from the tonsil. The result is that, instead of squarely grasping the gland at as deep a position behind it as before, the end of the tonsillotome slips over the back of the tonsil, and the operation results in simply slicing off a section from its top. To avoid this it is necessary to observe the rule that the blade of the instrument must always be kept parallel with the median line, and that if any deviation is made it should be to carry its distal extremity outward. Having engaged the tonsil in the ring of the instrument to the required depth, push the blade firmly and steadily through the included tissue, separate the fragment of tonsil, and, withdrawing the instrument quickly, remove the excised gland adhering to it. Then with the greatest possible expedition—and before the patient realizes that there is to be a second operation—before bleeding sets in, and without giv-

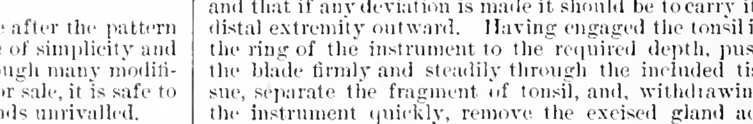

FIG. 4733.—Fahnestock's Guillotine. (Modified.) In the variety shown here the instrument consists of three principal parts: *A*, A ring made to receive the thumb of the operator, and attached to a rod upon the end of which are the pronged forks *D*; *C*, a staff, at the end of which is a ring, *E*; *B* and *B*, two rings made to receive the fore and middle fingers of the operator's hand, and attached to another rod which plays upon the staff *C*, and at the end of which is a ring-knife which rests within a groove in the ring *E*. In using the instrument the thumb-piece *A* is pushed forward for a certain distance, when by the automatic releasing of a spring-catch the rod with the knife attached is drawn forward by the rings *B*, *B*, so that the tonsil, already engaged in the ring *E*, and drawn still farther through it by the forks, is excised.

ing him a chance to cough or clear his throat—reintroduce the tonsillotome on the opposite side and remove the remaining gland. By this means both tonsils may be removed at one sitting, so that but one convalescence is to be endured. Few young patients will submit to a repetition of the operation. Several ingenious modifications of the Physick tonsillotome have been made, by which the handle may be reversed so that the operator may use it first in one hand and then in the other. A far better plan, however, is to gain through practice sufficient dexterity to change the instrument from one hand to the other, and to operate thus on both sides with equal facility. With a quiet and tractable patient the operation may be done very quickly, from ten to fifteen seconds being ample time in which to complete it.

In most cases the actual pain caused by cutting through the tonsil is very slight, the patient often complaining more of the introduction of the instrument into the pharynx and the consequent reflex than of the operation itself. The injection into the tonsil of cocaine is an undesirable procedure. General anæsthesia, from either chloroform or nitrous oxide, is objectionable, not only because it is, as a rule, unnecessary, but because it is desirable to have the active co-operation of the patient in clearing the throat the moment that the operation is completed. To this rule, however, there are exceptions. When a child is highly irritable, nervous, and timid, and when the operator may be tempted to abandon the case rather than subject the patient or himself to the inevitable struggle which with such children must be undergone, the administration of nitrous oxide will prove of great assistance. If the child is fairly well and strong, the best plan is to be frank with him, place him upon his mettle, and proceed with the operation. If, on the other hand, he is delicate and easily frightened, it will be wise to consider to what extent he may be coerced without producing an undesirable degree of shock; and, as chronic hypertrophy of the tonsils is apt to be associated with these very conditions of nervousness, such children should be managed with the greatest gentleness and consideration.

As hypertrophy of the tonsils is commonly associated with pharyngeal adenoids, the removal of both upon the same occasion under general ether anæsthesia has proved by far the best and most satisfactory way in which to deal with these cases.

According to most authorities, hemorrhage after the operation is usually slight and soon ceases spontaneously. If it persists it may be readily checked, and generally by simple means. Of the latter the most effective is the direct application to the cut surfaces of a mixture consisting of one part gallic acid and three parts tannic acid, reduced to the consistence of cream by the addition, drop by drop, of a small quantity of water. This or the sucking of cracked ice will usually prove effective.

The view taken by most specialists is, that the operation is attended with little or no real danger. On the other hand, there are some practitioners who look upon it with dread.

In reality, during the last twenty years, death from hemorrhage following tonsillotomy in patients under eighteen years of age has been extremely rare. Over eighteen several cases are recorded. Serious bleeding may occasionally occur. Moderate bleeding, requiring means to check it, is, on the whole, uncommon. In hemorrhage after tonsillotomy several varieties of bleeding may occur. These are:

1. Arterial: from the division of one or two comparatively large arterial branches.
2. Arterial: from the division of a large number of small arterial twigs.
3. Venous: from the division of the small plexus of veins which lies below and outside of the tonsil.
4. Capillary from the presence of the hemorrhagic diathesis.

Of the above varieties, the first two seem to be the most common.

Ligation of the carotid, common, external or internal, has generally proved ineffective.

Hemorrhage in general, it is unnecessary to say, is likely to cease during syncope. In bleeding after tonsillotomy, the excitement of the patient and the consequent stimulation of the heart and activity of the brain result in great increase in the general circulatory force and in the amount of blood actually carried to the brain. As long as this condition lasts bleeding will continue, the tendency being for it to grow more, rather than less, severe, even although the common carotid may have been tied. When, however, the heart's action becomes weak and the brain anæmic through syncope, bleeding from the tonsil will cease. This circumstance would, it seems, tend to prove the futility of ligating the common carotid.

In general, it may be said that the operation of tonsillotomy should not be performed unless ample means are at hand for controlling any ordinary amount of hemorrhage which may occur, and, although the chances of bleeding are infinitely slight, no surgeon is justified in incurring them unprepared. Since the amount of bleeding present may vary from the loss of a few drachms up to a hemorrhage of considerable importance, it follows that the means selected for its arrest must vary with the nature and severity of the case.

In the vast majority of instances, the bleeding, even though sharp at first, will subside spontaneously within a few minutes after the operation. In these cases the patient should be directed to keep the head upright, as far as possible; to refrain from making efforts at clearing the throat; to gargle the throat quickly, and several times in succession, with ice water; or, instantly upon the removal of the tonsils and, if possible, before bleeding has begun, the surgeon should apply to the wounded surfaces the tanno-gallic mixtur of Morell Mackenzie, already mentioned, all preparations for the application having been made beforehand.

Should the bleeding continue, grasp a smooth, rounded piece of ice in a pair of long forceps and hold it firmly against the bleeding surface. Or wrap, somewhat tightly, a pledget of absorbent cotton around the end of a suitable rod, saturate it with the tanno-gallic mixture, and then press it against the wound. In any case the pharynx of the patient should be illuminated by the best attainable light, the neighborhood of the tonsil diligently cleared of clots, the cut surface thoroughly exposed to view, and careful search made for the exact source of the hemorrhage. Sometimes this precaution will be rewarded by the discovery of one or two spirting points. These will generally be found low down in the pharynx, corresponding with the inferior part of the tonsil, in which the larger arterial branches seem to be received. Such points, having been discovered and precisely located, should be seized with long slender forceps and thoroughly twisted; or they may be touched with a small galvano-caustic point; or the tip of a probe upon which nitrate of silver has been fused may be pressed into them, the spot having previously been well cleared of blood.

Such hemorrhage is apt to occur in cases in which the incision has been carried low down in the pharynx, and may usually be arrested by the above means. Upon inspecting the thoroughly cleansed wound, however, there may appear innumerable little vessels, none of which is large enough to be seized, but all vigorously bleeding. These are the cases in which the fibrous stroma containing the nutrient vessels is markedly increased and the vessels themselves are large and abundant. Encased as they are in fibrous tissue, it is difficult for them to contract; hence the bleeding, abundant, persistent, and exceedingly difficult to control.

In these cases the ordinary means for stopping hemorrhage are often ineffective. The iron styptics are worse than useless, while the cautery only seems to make the bleeding worse. If the tonsil has been thoroughly removed, there is nothing left around which a ligature may be applied.

About the best suggestion for such a case is that of Levis, who transfixes the bleeding base with the hook of a small tenaculum, performs torsion, and directs the patient to hold the flat handle of the tenaculum fixed between his teeth. By passing a bandage around the head and under the chin this position may be maintained for many hours. The method has proved very effective. Pressure of the common carotid may be maintained, although in the personal experience of the writer and of others it has often proved useless. Meanwhile, several general measures of great value may be employed.

Since the object desired is to quiet the circulation and allay nervous excitement, the administration of opium is decidedly indicated.

Arterial tension may be relieved by shutting off a part of the supply of blood. This may be accomplished by constricting the patient's thighs, as is sometimes done in hæmoptysis.

Finally, in most instances of tonsillar hemorrhage of the class last described, the bleeding has continued in spite of all efforts to stop it until, at last, the patient has fainted. Upon the occurrence of syncope the flow has promptly ceased, nor has it, with the return of consciousness, recurred. While, therefore, the means which seem best adapted to the case in hand are being applied, any tendency to fainting should be encouraged rather than repressed. Should the above means all prove ineffective, and the question of ligating one of the great vessels be entertained, it should be remembered that ligation of the internal carotid is useless; that ligation of the common carotid has sometimes succeeded, but has often failed; and that the choice of a successful operation lies between tying the external carotid near the bifurcation of the common carotid, or the ligation of both the common and the internal carotid arteries.

The occurrence of a venous hemorrhage is unusual. The writer has seen one such case, which was checked without great difficulty by means of cold and pressure.

Capillary hemorrhage may be stopped by the tannogallic mixture, by pressure, by cold, or, finally, by the gargling of water taken as hot as can be borne.

Of a very large number of cases of tonsillotomy known to the writer, in only one has severe hemorrhage occurred in a child. This patient had hæmophilia. Recurrence of the bleeding was evidently caused by the swallowing of food. The patient was nourished by rectal alimentation for three days, with complete success.

Finally, annoying and persistent bleeding may occur from the accidental wounding of the anterior pillar of the velum palati in the course of tonsillotomy. The adhesions which often exist between the anterior pillar and the tonsil should be broken up before the removal of the gland is attempted.

The after-treatment in tonsillotomy is exceedingly simple. The general condition may be estimated to equal about that of a patient suffering from a mild attack of tonsillitis. He should be kept quiet for two or three days. Solid food should be withheld for thirty-six hours, and then such articles selected as shall produce neither chemical nor mechanical irritation. A gargle of simple borax and water, or containing besides a trace of carbolic acid or thymol or some other good disinfectant, should be used after the first day, unless it causes pain in the throat, in which case the fluid should be used with an atomizer. Gum arabic may be occasionally dissolved in the mouth. The wound usually heals with rapidity and without accident. Sometimes, however, in unhealthy subjects infection from some of the numerous bacteria of the buccal cavity takes place and it becomes covered with a thick, whitish membranous deposit, which may even appear to be diphtheritic, and which may be associated with more or less constitutional disturbance. This, in the majority of cases, soon yields to local disinfectant measures, and the internal administration of iron.

In addition to the healing of the pharyngeal wound, in the case of children, three points at least (in addition to the general tonic treatment sometimes required) should be carefully attended to:—

First, the mouth-breathing habit must be overcome, even when the pharyngeal obstruction has been removed. To this end the patient should be encouraged, while waking, to breathe through the nose. When asleep he may need the benefit of some artificial help.

Secondly, the defects of pronunciation commonly met with in the subjects of enlarged tonsils, become, like the mouth breathing, matters of habit, and do not always disappear when the condition upon which they depend has been relieved. This matter should be explained to those having the child in charge, and suitable exercises in reading and pronouncing recommended.

Finally, the deformity of the chest will in many cases need attention. Light gymnastics and, more particularly, the systematic practice of chest expansion, will often bring about a surprisingly rapid and beneficial result.

The results of tonsillotomy are immediate and marked, and the child who was before weak, ill nourished, underdeveloped, will in many cases begin to grow with remarkable rapidity; his whole appearance at the end of several months being greatly changed for the better.

It is not easy to understand why the excision of enlarged tonsils should meet with the opposition which is sometimes brought to bear against it. Still less is it explicable when the ground of the opposition is explained.

Among the principal objections which have been urged against tonsillotomy are the following:

1. That the tonsils will atrophy spontaneously at puberty; or, as some express it, that the child will "grow to his tonsils."

2. That tonsillar hypertrophy exercises a protective influence against infections. Also, that it protects against bronchitis and phthisis.

3. That the removal of the tonsils will injure the voice.

4. That their removal will impair the patient's virility.

5. That the tonsils will be likely to grow again.

6. That milder measures than excision will answer the same purpose.

7. That the operation should be indefinitely postponed because the patient may be weak.

In every one of the seven objections quoted the objection is absolutely and exactly contrary to the truth.

Foreign Bodies in the Tonsils.—From their peculiar structure and position, the tonsils are prone to the arrest and lodgment of small pointed foreign bodies. These may be found fixed in one of the deeper lacunæ or thrust into the substance of the gland itself. Their presence is characterized by a limited degree of pain at the seat of impaction, and sometimes by slight dysphagia. Occasionally, however, the pain is referred to a point more or less remote.

Commonly, in tonsils which are the seat of chronic inflammation, the secretion of the lacunæ may be increased in quantity and retained within the crypts, as before described in this article. These soft concretions, which are of a white or yellowish color and cheesy consistence must not be mistaken for tonsillary calculi, which are entirely different both in character and in composition, and which are actually of rare occurrence. The composition of such concretions is principally phosphate and carbonate of lime. They are, therefore, not of gouty origin, as has sometimes been supposed. Besides the above-named salts, they contain small quantities of iron, soda, and potassa. Their presence gives rise to few symptoms which may not be observed in any inflamed tonsil. A slight pricking sensation is often complained of, and, when the concretions are large, there is dysphagia. Sometimes small concretions are discharged spontaneously, and sometimes their presence predisposes to severe attacks of quinsy, in the course of which an abscess may form which may be very slow in healing. The presence of a tonsillar calculus may be determined by the discharge of pieces of the calculus, by inspection, a part of the calculus projecting from the lacuna far enough to be visible, or by direct examination with the finger or a probe.

In the treatment of these cases the concretion may be removed by means of a hooked probe, or by small forceps. It will generally happen that the tonsil will be enlarged, and then the extirpation of more or less of the gland will be called for. Indeed, this is the simplest way of relieving the whole trouble. The use of the tonsillotome may be impossible on account of the hardness of the calculus; in which case resort to the bistoury will be necessary.

Parasites in the Tonsils.—Mackenzie quotes several instances in which certain parasites, such as hydatids and trichocephali, have been found in the tonsils. Dupuytren relates the case of a woman twenty-one years of age, who for eleven months had suffered from attacks of inflammation of the tonsils. The left gland was considerably swollen, and the surgeon having diagnosed an abscess, plunged a bistoury into the tumor. As a result, nearly two ounces of watery fluid gushed out, and ultimately a large hydatid cyst, the size of a hen's egg, was extracted. The patient died soon after, and a hydatid cyst, the size of a child's head, was found attached to the left kidney. A similar case, excepting that the patient was a man, is reported by Davaine, and the same observer relates an instance in which a trichocephalus was found lodged in the left tonsil. The parasite had probably attained this situation through being expelled from the stomach during the act of vomiting.

SYPHILIS OF THE TONSIL.—*Chancre.*—Chancre upon the tonsil is occasionally observed. While chancre of the lips and buccal cavity is not uncommon, its occurrence on the wall of the pharynx is practically unknown. The explanation of its appearance upon the tonsils is plain when the structure and position of those organs is remembered. There are many cases in which, without question, it has been innocently acquired. While chancre of the tonsil is generally unilateral, it has sometimes been observed upon both glands.

The diagnosis of chancre of the tonsil is apt to be difficult, since the symptoms vary considerably, and the situation of the trouble is so remote that it easily passes unobserved or unrecognized.

The signs of infection generally begin with slight redness and swelling, and without perceptible induration. Soon there are pain in deglutition, increased redness, and hypertrophy, which is followed by a superficial erosion, having an indurated base, and more or less glandular involvement of the affected side. The hypertrophy and general tumefaction of the tonsil itself are important signs, and seem to be a constant accompaniment of the disease. The second important symptom is the superficial erosion, increasing to an actively ulcerating surface, generally covered with a grayish-white coating of greater or less thickness, granular in character, and distributed over the surface of the ulcer in a somewhat irregular manner. Sometimes the erosion is very superficial and ill-defined, while in other rare cases it has assumed the phagedenic form, presenting a deep, sloughing ulcer, with a high degree of inflammation and tumefaction of the neighboring parts.

Induration of the base of the ulcer is not a constant factor. In many cases it is conspicuously absent. Ptyalism is an early and marked symptom.

Enlargement of the submaxillary lymphatic glands of the affected side is a constant symptom, the engorgement being hard, indolent, and sometimes extensive. Suppuration does not seem to have been observed. The duration of chancre of the tonsil has been thought to be shorter than that of the same lesion in other places. There is more or less dysphagia, often severe, and, when the ulceration assumes the phagedenic form, pain in swallowing may become very severe.

The immediate diagnosis of chancre of the tonsil is often by no means easy. It will generally be difficult to obtain a history of contagion, through either the reticence or the ignorance of the patient. The unusual situation of the lesion, its diversity of appearance and form, the absence of corroborative evidence, all render the case in many instances obscure. It is necessary to differentiate it from malignant disease, especially epithelioma; from tuberculous ulceration; from psoriasis of the mouth and from the so-called smoker's patch; from mucous patches; from the ulcerating gummata of tertiary syphilis; from diphtheria; and, finally, from gangrenous ulceration of the tonsil.

It is often impossible to arrive at a decided conclusion until the development of constitutional phenomena and the results of treatment unite in confirming the diagnosis. The treatment, constitutionally, must depend upon the views of the practitioner with regard to the management in general of early syphilis. Should mercury be administered, the cyanide, one-sixteenth of a grain three times daily, as recommended by Morell Mackenzie, has been found especially valuable by the writer. In simple cases emollient gargles will answer every indication; while, if the sore becomes phagedenic, cauterization with the acid nitrate of mercury and the application of antiseptic sprays or gargles will be indicated.

Erythema of the tonsils is common in early syphilis. It may be general at first, but soon shows a disposition to limit itself by well defined margins and to assume a symmetrical arrangement.

Mucous Patch.—The occurrence of mucous patches upon the tonsil is very common, especially in cases in which the tonsils have already been hypertrophied and inflamed. They may be slight and barely perceptible, or large, well defined, and extensive, varying in color from an opalescent grayish-white to a dull yellow. In the latter case they are often mistaken for the exudation of follicular tonsillitis and for diphtheria, from which they may readily be distinguished by their chronicity, their appearance, and by the history and coexisting signs of syphilis. The tonsils themselves meanwhile are generally much enlarged and inflamed. Local treatment is best carried out by applications, to the patches, of solutions of iodine, and by cleansing sprays or gargles. For the erythema an astringent spray will hasten resolution.

Gummy tumor may be recognized by the characteristic appearance of the ulceration; by the comparative freedom from pain, which distinguishes it from cancer and from tuberculosis; by the absence of the signs characteristic of tubercle in other parts of the body, including the high evening temperature; and by the fact that in the latter disease the ulcers are smaller and less deep. The best effects may be obtained from the internal administration of the iodide of potassium, while, locally, the progress of the ulcer may be checked by applications of the nitrate of silver or the acid nitrate of mercury. Indolent ulcers may be stimulated by means of solutions of the sulphate of copper, or of the sulphate or chloride of zinc.

TUBERCULOUS ULCERATION.—Tuberculous ulceration occurring primarily in the tonsil is rare. Consecutive to the appearance of the disease in other organs, it is not very uncommon, a fact which may be explained by the position and vulnerability of these organs. The appearance of the ulcer, when not too broken down, presents most of the following characters: The surface is uneven, pale, and devitalized; it is granulated or often covered with yellowish-gray, viscid or coagulated mucus; the edges are sometimes sharply cut, sometimes levelled, seldom elevated, everted, or undermined; the surface is not usually very red, but often more reddened than the surrounding tissue; there is little or no surrounding induration; the shape of the ulcer is not constant, but it is usually ovoid; its depth varies, but it is usually superficial; there is generally ulceration of some of the neighboring parts; pain in swallowing is usually very severe.

As to the local treatment of these ulcers, much will depend upon the stage of the general disease and the condition of the surrounding parts. Primary ulceration is best treated by the destruction of the infected area, either by scraping or by means of the galvano cautery; this should be followed by applications of lactic acid or of a solution of iodine, the healing process being encouraged by any suitable means. When the ulceration is secondary to general tuberculous infection and to the development of ulceration in neighboring parts, less vigorous means will probably be indicated.

In these cases the best results have been obtained by first spraying the surface of the ulcer with a solution of resorcin of a strength of two or three per cent., or with a weak dilution of Dobell's solution, and then applying to it lactic acid. If cocaine has been previously used the last application is painless. The strength of the lactic acid may be made to vary from thirty to one hundred per cent. In many cases the application of a four-per-cent. solution of cocaine will be found effective in relieving the intolerable pain and dysphagia. Anæsthesine and orthoform are both good local sedatives, as is also morphine, and they are to be preferred to cocaine in many cases. Treatment, to be effective, must be carried out with great thoroughness and regularity, and the general nutrition of the patient must be maintained with care.

Pharyngomycosis.—A parasitic disease which affects the tonsils rather more frequently than other parts will be described in the article on *Mouth, etc.*, in The Appendix.

Tumors of the Tonsil.—*Benign.*—Benign growths springing from the tonsil are somewhat uncommon. The varieties most frequently met with are papillomata, fibromata, lymphomata, lipomata, and angiomata. Papilloma of the tonsil is similar to the same growth in other parts of the body. Such tumors are generally of small size. They are apt to spring from the upper part of the tonsil, and to be pedunculated, creating little or no disturbance by their presence until they attain dimensions sufficient to render them mechanically irritating. Their appearance is that of a warty growth, with irregular outlines, their consistence is soft and yielding, and their color usually pink.

Fibromata are very similar to the above, excepting that they develop from the peritonsillar connective tissue, appearing like polypoid growths, or, as happens occasionally, growing in the connective tissue of the gland itself. The surface of the tumor is smooth and glistening, and its consistence is firm. In the case of papillomas and fibromas which are pedunculated, the best treatment is to put the pedicle well upon the stretch and then divide it close to the healthy membrane by means of a galvano-cautery knife.

Lipoma, or fatty disease of the tonsil, is rare. There are no gross features which particularly distinguish it, so that a diagnosis must be made by the aid of the microscope.

Lymphoma, although histologically similar to simple hypertrophy, is generally associated with leucocythæmia and general lymphadenitis. It is sometimes seen as a consecutive manifestation after the neighboring glands have become enlarged. Suppuration of the tonsils in this condition rarely occurs. When thus affected, the tonsils attain such a size that they obstruct the pharynx and are otherwise annoying, they may be excised. The advantages of the operation, however, will be largely mechanical.

Angiomatous tumors of the tonsil and nævus of the same organ, although sometimes observed, are exceedingly rare.

Malignant Growths.—Although not a favorite seat for the development of malignant growths, such tumors occasionally appear in the tonsils, and occurring there they are, from their history and prognosis, of the utmost importance.

Primary cancer of the tonsil is rare. Of the two principal types, sarcoma and carcinoma, the most common is the round cell sarcoma. In addition to this are found the spindle-cell sarcoma and the lympho-sarcoma.

Of carcinomas the squamous-celled or true epithelioma is the most common. While the sarcomas and spheroidal carcinomas generally form distinct and prominent tumors, growths of the epitheliomatous variety break down more or less early in their course and form deep and sloughing ulcerations. The symptoms of cancer of the tonsil are more pronounced in the carcinomatous varieties. In the latter, pain of an intermittent and lancinating character is usually an early and pronounced sign. Dysphagia soon follows.

In some cases, however, pain is not experienced at the seat of the difficulty, but is reflected to other parts of the throat. Such, for example, are cases in which otalgia, due to reflex irritation from malignant disease of the pharynx, has been treated locally for some time before attention was directed to the difficulty in the throat.

Whatever the nature of the disease, its progress is marked by infiltration of the adjacent structures, most often the soft palate or palatine arches.

The course of the disease is rapid. Both in sarcoma and in carcinoma the cervical glands are almost invariably involved, and early in the history of the case.

Cancer of the tonsil may be secondary to the appearance of the disease in other organs. In a case of extensive sarcoma of the tonsil operated upon by the writer, the disease was multiple. The tumor of the tonsil was large, smooth, and resisting, and it filled the pharynx and overhung the larynx to such a marked degree that deglutition and respiration became impossible. It had been of slow growth and its removal was attended with marked and long-continued relief. In several cases of sarcoma mentioned by Butlin the immediate cause of death was hemorrhage, both in those not operated upon and in those which were recurrent. In other cases death is caused by exhaustion due to dysphagia and sepsis, or to a combination of various causes, among which the secondary involvement of other organs plays an important part.

Hemorrhage from the ulceration of an epitheliomatous growth is not common.

The diagnosis of malignant growth of the tonsil is, generally, not difficult. It is unusual before middle life. It is unilateral. Pain, either local or reflex, and enlargement of the glands at the angle of the jaw are almost constant symptoms. As between epithelioma and sarcoma, the diagnosis is not always easy. In the former, however, pain is apt to occur earlier in the progress of the disease and to be more severe, while the tendency to ulceration rather than to the formation of a considerable tumor distinguishes epithelioma from sarcoma, which at the same time is slower in growth, much more firm in consistence, and likely to attain a much larger size.

The microscopical findings are often unsatisfactory, as the growth is apt to develop in the deep tissues, so far away from the surface that a specimen for examination cannot be obtained, and long before the surface has become involved the diagnosis may be made from the clinical signs.

The prognosis is bad, especially in epithelioma, as few patients live more than a year. It is more serious, of course, when glandular involvement has taken place, or when the neighboring structures have become infiltrated.

Treatment.—In the treatment of these cases, both the sarcomatous and the carcinomatous, an early diagnosis is of the first importance; and this is particularly the case if the disease of the tonsil be primary. For, while removal of the tonsil by the natural passages is by no means a difficult operation, the reverse is true of the extensive operation required for its removal from the outside. Thus far, neither the *x*-ray nor the toxins of erysipelas have succeeded in curing cancer of the neck. The application of the *x*-ray, however, is generally productive of positive results in relieving pain, in diminishing the secretions of the part, and in actually retarding the progress of the disease. For these reasons alone its application seems desirable, especially in cases otherwise beyond remedy. Aside from palliating the condition, little can be expected from any course of treatment which is not surgical in its nature. The local application of astringents and the internal administration of various drugs calculated to delay the progress of the disease, can only succeed to a slight degree in accomplishing the desired result.

For the removal of the tonsil several methods have been proposed. The one selected must depend mainly upon the character of the disease and the presence or absence of involvement of the lymphatic glands. The tonsil may be removed either from within the mouth, or through an opening in the side of the neck. When the lymphatic glands are enlarged, removal of the organ through the mouth can be regarded as only palliative.

Removal through the natural passages may be justifiable under certain favorable conditions, such as a slowly growing tumor, plainly located in the tonsil itself, and accessible through the mouth, and in the absence of glandular involvement. Some of the sarcomas reported as successfully cured have been of this description.

In operating the surgeon should anæsthetize the patient through the medium of a tube or some similar apparatus, introduced at the side of the mouth or through the nose; the mouth must be widely separated with a gag, and the patient's head should be slightly raised and turned toward the best light obtainable.

Excision of the affected tonsil may be best accomplished by means of a galvano-caustic knife, a galvano-caustic loop, or a cold-wire écraseur. Of these methods, the galvano-caustic écraseur will probably prove most useful in the majority of cases. While the cold wire may be used, with almost no hemorrhage, the galvano-caustic écraseur accomplishes as much and possesses besides several advantages over it. The amount of tension required for the latter is small, so that the loop is not apt to be dragged from its place, and fixation needles, if they are used, are not torn from the tumor by the pressure of the wire From the effect of the cautery any remnant of the growth is apt to be destroyed at the time of the operation, and the chances of recurrence are thereby lessened.

Care should be taken not to allow the temperature of the wire to rise too high, for the slower its progress the less will be the liability to hemorrhage. Usually bleeding is slight. Instead of the methods just described, the enlarged mass may sometimes be efficiently enucleated by means of the finger of the operator.

In cases of severe hemorrhage, and when there is considerable obstruction of the larynx from the effects of the tumor, immediate or remote, the performance of tracheotomy may be necessary. Whether or not a tampon-cannula should be used must be determined by the necessities of the case in hand. When the larynx is obstructed to any extent by the growth, or when the rima glottidis has been narrowed by œdema or otherwise, the wisest course will be, probably, to perform a preliminary tracheotomy. No unnecessary time should be consumed in inserting the tracheal tube. Should bleeding occur the best hæmostatic is the galvano-cautery. In operating upon such cases great assistance in illuminating the pharynx may be obtained by means of a small incandescent electric light.

Even in certain cases in which the disease of the pharynx has extended beyond the tonsils to the soft palate and base of the tongue, the operation through the mouth with the galvano-cautery has been successfully employed. In advanced cases, however, and in those in which the cervical glands are involved, the above operation can only be palliative.

Removal of the tonsil through an incision in the neck was first proposed and practised by Cheever, of Boston. Valuable modifications of it have been made by Czerny and by Mikulicz. Unfortunately, recent statistics relating to these operations do not exist. The cases themselves are rare and the unfavorable ones are seldom reported, so that it is impossible to know with any accuracy the actual value of the radical operation. In view of the necessarily fatal termination of the disease, however, if left to itself, it is encouraging that in some cases at least a cure has been effected, McBurney and other surgeons having instances to their credit in which the patient is alive and well several years after operation.

II. PHARYNGEAL TONSIL, OR LUSCHKA'S TONSIL.

Lymphoid hypertrophy in the upper pharynx was noticed by Schneider as early as 1655. Prof. Wilhelm Meyer, of Copenhagen, was the first, however, to estimate it at its true value, and to propose efficient means for its relief. His first article on the subject, published in 1868, is classic.

Luschka's tonsil is susceptible of two classes of difficulty. The first of these is an acute or subacute inflammation, attended with temporary enlargement, the said enlargement subsiding with the disappearance of the exciting cause. While this cannot be called a true hypertrophy it is a lesion of great importance, both on account of the temporary inconvenience which it causes and also by reason of the tendency which it manifests to leave behind a permanent enlargement of greater or less degree.

This permanent or chronic enlargement in the course of time constitutes a true hypertrophy, and, although its actual degree may vary under the general influences which cause it to grow better or worse it seldom entirely subsides. Chronic hypertrophy, as commonly met with, is clinically of two varieties. In the first the adenoid element predominates. The consistence of this variety is one of its chief characteristics, for it is soft to the touch, friable, easily broken up, and shows a tendency, when torn away, to separate in large spongy masses.

In the second variety the hypertrophied mass is composed more largely of fibrous tissue elements. Operation upon the latter variety is more difficult than upon the former, as its dense structure offers greater resistance to the efforts of the surgeon, which, when successful, result in the removal of but small masses of firm tissue, in marked contrast to the large fragments which are easily torn away in cases representing the variety first mentioned.

The location of the growth is of practical importance, both as regards its effects and as to the comparative difficulty of its removal. Its size may be so great as practically to fill the retronasal space, or, on the other hand, it may be so slight as to make it difficult to determine whether or not its condition is pathological. The hypertrophied tissue may be confined strictly to the vault, or it may be diffused over the posterior and lateral walls of the pharynx, or upon the posterior wall of the pharynx alone, in a large, well-aggregated, tumor-like mass.

The symptoms have already been described in dealing with the subject of obstructed nasal breathing (page 815).

The diagnosis of lymphoid hypertrophy at the vault of the pharynx is usually easy, the symptoms being sufficiently apparent in most cases to suggest at once the nature of the difficulty. The diagnosis is established by examination of the upper pharynx. This may be accomplished by one of several methods.

1. *Posterior Rhinoscopy.*—The upper pharynx may be demonstrated by the mirror, even in children of four years old, if sufficient patience and skill be exercised. This method is highly desirable, as it does not alarm the child.

2. *Palpation.*—With the tip of the forefinger carefully inserted into the pharynx the presence of hypertrophied tissue can be accurately demonstrated. Great care should be taken not to inflict pain nor cause injury. The end of the finger should be carefully prepared for the purpose, and the mistake of trying to insert a finger-tip too large readily to enter a small pharynx should be avoided.

3. *The Probe.*—In very young children a probe, made of a very small English woven bougie, may be passed into the pharynx and the presence of hypertrophied tissue thus demonstrated.

4. *By Anterior Rhinoscopy.*—A strong light thrown into the nasal cavity may sometimes bring to view the thickened masses at the upper and posterior part of the pharynx.

In very young infants three diagnostic points may be observed, namely, mouth-breathing, snoring, and inability to perform the act of nursing without stopping to take breath. All of the above are due to nasal obstruction.

The symptoms commonly met with in lymphoid hypertrophy have already been described in the earlier part of this article. In addition to them should be mentioned the effect of disease of the faucial and pharyngeal tonsils upon the cervical lymph nodes. These are often caused to become inflamed, to swell, and to suppurate from absorption of various septic organisms originating in the tonsils. When glandular swellings of the neck are found to occur, either in occasional exacerbations or chronically, examination of the pharynx should always be carefully made. The removal of diseased tonsils in such cases, unless performed too late, is followed by remarkably beneficial results.

The treatment of an hypertrophied Luschka's tonsil must depend in some degree upon the nature of the growth, the size to which it has attained, and the age of the patient. In a few instances, in which the disease is

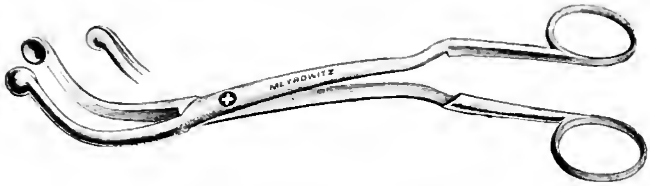

FIG. 4734.—Loewenberg's Forceps, modified.

acute or subacute, where the tissue is soft, and where the growth is small, or finally, where the patient is old enough to submit to local treatment, the application of resorptives and the administration of alterative and tonic medicines, together with careful attention to hygiene, may accomplish a cure. Almost invariably, however, these means will be found unsatisfactory, and the question of radical measures will present itself.

As to the methods by which the offending tissue may be removed the use of local applications for the reduction of adenoids has not yet been a success. The attempt to reduce them also by escharotics is highly objectionable, as both with the ordinary caustics and with the galvano-cautery much difficulty is experienced in making the application and great danger is incurred of injuring important neighboring structures. Hence some form of surgical operation seems in the present state of our knowledge to be unavoidable.

The relative thoroughness and safety with which an operation can be performed will depend somewhat upon the kind of instrument employed. It is necessary therefore that the instruments commonly used for the purpose should be described.

Beginning with the finger-nail and Meyer's ring knife, an almost unlimited number and variety of instruments for the removal of hypertrophied lymphoid masses have been devised. They may be classified into several groups—namely, those made upon the principle of (*a*) the curette, (*b*) the forceps, (*c*) the wire loop, and (*d*) the adenomatome.

(*a*) The curettes are of three kinds: The ring knives of comparatively small size, the sharp spoon, and the Gottstein instrument. To this class may be added the finger nail.

(*b*) The forceps include those instruments which are constructed with comparatively blunt edges and which are intended to tear away the tissue rather than to cut through it. Of these, the Loewenberg is the best example. Many modifications of it have been made, some of which are very satisfactory.

(*c*) The wire snare or loop has been used by some, either in a simple curved canula or in an instrument especially designed for the purpose. While it has possibilities of usefulness, it appears that they have not yet been fully realized.

(*d*) By the name adenomatome is meant an instrument constructed more or less upon the principle of the scissors and intended to make a clean incision through the substance of the growth.

Nature's instrument, the finger nail, is undoubtedly useful in completing the work of other implements by the separating of partly detached fragments of tissue and by the removal of it from corners difficult for an instrument to reach. Gottstein says: "It is clear that with the finger only a very little can be removed, and, moreover, it must be recognized that from the point of view of asepsis the finger nail is a decidedly undesirable instrument." The artificial finger nail is practically never used.

Of the curettes, the small ring knives are valuable for the removal of limited areas of tissue, especially those left after operation with larger instruments. They are also very useful for operations upon the adult, where, under local anæsthesia and with the aid of the mirror, small quantities of tissue can be removed at a time with comparatively little pain and irritation.

The sharp spoon has been justly condemned because of the amount of bleeding which it causes and the difficulty experienced with it in separating the fragments of tissue from the pharyngeal wall.

Of the instruments of this class, Gottstein's knife (Fig. 4736) and its modifications must claim the greatest popularity. There are several things to be said in its favor.

If pain is of no account and speed of more importance than thoroughness, then Gottstein's knife would be ideal. The objections to it, however, are serious, for its use is painful, and it is seldom that the shape of the instrument is so perfectly conformed to the pharynx, the base of the growth so limited in its extent, and the management of the knife, so well directed, that the necessary thoroughness can be attained. It will often be found that the Gottstein knife has simply cut through the lower part of the growth, or has removed a certain amount from one side, leaving the other side full, or has fairly cleared the vault, leaving abundant deposits upon the posterior and lateral pharyngeal walls.

In the forceps, modified to suit the size of the pharynx and the location of the growth, we have an instrument by which the lymphoid masses can be seized and, by proper manipulation, torn away, much larger fragments than the part caught in the grasp of the instrument usually being separated at each attempt. In skilled hands the forceps can be turned in all necessary directions and its blades made to grasp everything in their way. The pharynx can thus be thoroughly cleared, and with the loss of less blood than is common with sharp instruments. The operation, however, is painful.

It would appear that the prime object of the adenomatome is to enable the operator to remove the whole or as much as possible of the growth at one introduction of the instrument. Many varieties of them are of large size or of improper shape, and are not fit to be inserted into the nasopharynx, while their great strength places at their mercy any object which they may grasp. Even in experienced hands they are probably the most dangerous of this class of instruments. As to their thoroughness, one glance at the construction of their blades will show that there must be certain parts of the pharynx which they cannot possibly reach, while the risk of cutting too deeply or in wrong directions is evident. Such instruments are better suited to adult cases and can hardly be intended to be used upon the child.

FIG. 4735.—Hooper's Palate Retractor.

Of the instruments described, the ones most generally useful are some good modification of the Loewenberg forceps and the sharp curette. A recent addition to the latter consists of an attachment by which the detached fragment of tissue is seized and thus prevented from falling into the patient's throat on the withdrawal of the knife. In general, the instrument used should be adapted as well as possible to the size and shape of the pharynx and to the particular growth to be removed. The importance of the structures adjacent to the pharynx calls for great care and skill in operations in this region.

The other instruments necessary for operating under anæsthesia are, a mouth gag and a retractor for the soft palate (Fig. 4735). The latter should be made of hard rubber, with a shank broad enough to protect the uvula from injury during the progress of the operation.

The position of the patient during operation is of considerable importance. Two methods are in common practice. In the first, the child is held upon the lap of an assistant in the sitting posture, with the head upright and turned toward a good light. The head is steadied by a second assistant, who also manages the mouth gag. The soft palate may be drawn upward by means of the palate retractor, or it may be secured by tapes passed inward through the nose and outward through the mouth and the ends tied outside after Wales' method. With the head inclined forward in this position the blood caused by the operation will tend to escape from the mouth instead of being swallowed. Moreover, the pharynx can be well illuminated and the steps of the operation better directed by the aid of vision. The position upon the back is preferred by many good operators, requiring, as it does, the services of fewer assistants and being the one to which a large majority of surgeons are better accustomed. It is not so favorable as regards the admission of light to the pharynx, and therefore it requires a greater degree of skill on the part of the operator, whose tactile sense must be highly educated by way of substitute. Blood, instead of flowing out of the mouth, is swallowed into the stomach. This is not a disadvantage, for it trickles down the posterior wall of the pharynx and escapes into the œsophagus, almost without making its presence felt, unless the flow excited has been considerable.

FIG. 4736.—Gottstein's Sharp Curette.

A possible objection to the upright position is the additional risk of fragments of detached tissue falling into the larynx and thus causing asphyxia. Such an accident has been reported. It is not probable that it could occur under the use of the forceps, although it is by no means impossible with the ring knife.

The management of the palate retractor as well as of the anæsthetic should be intrusted to a skilled assistant, as upon this the convenience, and, to some extent, the success of the operator, will depend. Great care should be taken to place the retractor in such a position that the antero-posterior diameter of the entrance to the upper pharynx be made as wide as possible, and that the most perfect protection be afforded to the uvula. Preliminary to operation the most thorough rhinoscopic examination possible should have been made and the situation, form, size, and texture of the growth well studied. Where this is impossible, examination by means of the finger is admissible, and digital exploration of the pharynx should always be made after the child has been anæsthetized and immediately prior to the operation. Should the growth be large and its attachments not easily demonstrated by the finger, a curved probe will lend useful aid in mapping them out. By the practice of careful preliminary examination a fair idea of the amount of tissue to be removed may be gained and if, during the operation, the fragments removed be preserved, it will be easy to estimate what part of the growth has been withdrawn and how much of it still remains.

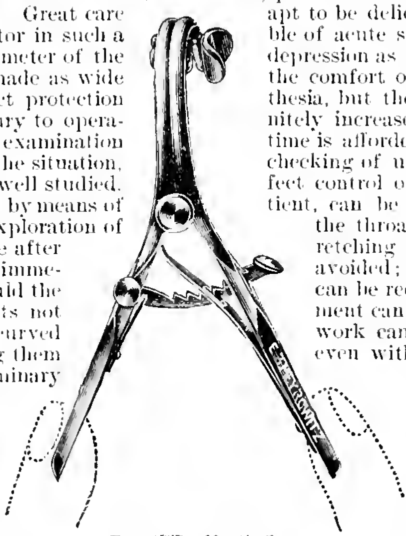

FIG. 4737.—Mouth Gag.

The removal of adenoid tissue from the pharynx is attended with more or less bleeding, and this, while generally of no importance, may sometimes be considerable. It is best, therefore, that the tissue be torn away, rather than cut. This method has the additional advantage of greater thoroughness. Remnants of adenoid tissue left behind by the forceps may be removed by the finger nail of the operator, by Hooper's modification of the Loewenberg forceps, or by means of a small carefully guided curette. Should the removal of a mass of adenoid tissue be followed by undue bleeding it is well to defer further attempts at operation for a few moments, until the hemorrhage shall have ceased, or, at least, until it shall have sufficiently diminished. Too great force in the separation of a fragment of tissue must be avoided. It is better to release the mass included in the grasp of the forceps and seize a smaller portion, or else, by applying the instrument in a somewhat different position, to separate adherent fragments than it is to attempt to accomplish too much at once. To prevent laceration of the mucous membrane in the removal of a fragment of adenoid tissue the tip of the forefinger should be passed upward and under the jaws of the forceps, and firm pressure made against the inferior attachment of the mass while the latter is being detached. As large masses of hypertrophied tissue often exist upon the posterior wall of the pharynx as well as upon the vault, it is necessary to secure the removal of this with the rest. The corners of the upper pharynx also, immediately above the Eustachian prominences, must be carefully cleared.

The manipulation of the instruments used in this operation as well as the *tactus eruditus* necessary to the clear understanding of what is being done, are accomplishments which, of course, are best gained by practice and experience.

In operating upon the upper pharynx anæsthesia is of the greatest possible value both to the physician and to the patient. The almost universal testimony, both from children and adults, is to the effect that the removal of adenoid tissue from the pharyngeal vault is exceedingly painful. Exceptions to this are occasionally met with, and in the case of the strong and phlegmatic, and where the growth is soft, it may be well to dispense with a general anæsthetic in favor of cocaine. As a rule, however, patients who suffer from adenoid hypertrophy are apt to be delicate, nervous, and timorous, susceptible of acute suffering, and likely to undergo much depression as the result of operation. Not only is the comfort of the patient secured through anæsthesia, but the convenience of the operator is infinitely increased. With general anæsthesia ample time is afforded for careful examination and for the checking of undue bleeding should any occur; perfect control of the operation, as well as of the patient, can be maintained; thorough relaxation of the throat can be secured; the inducement of retching from pharyngeal irritation can be avoided; troublesome remnants of the growth can be recognized and removed; undue excitement can be prevented; and, finally, the whole work can be accomplished without pain and even without the slightest knowledge on the part of the patient of what has been done.

Again, the safety of the surrounding parts is far more likely to be sacrificed when the operation is done hastily upon a struggling child. Serious injury has thus been inflicted upon the posterior edge of the nasal septum, the turbinated bodies, the Eustachian eminences, and the lateral and posterior walls of the pharynx. The more humane the method of operating, the more will the work of the operator be facilitated and the best interests of the patient secured.

The anæsthetics suitable for such cases are, for local anæsthesia, cocaine, and bromide of ethyl; for general anæsthesia, ether, chloroform, and nitrous oxide gas. The advantages of cocaine are that it renders the introduction of the instrument into the upper pharynx much easier and diminishes the pain and local spasm otherwise sure to occur. Its disadvantages are the length of time which it takes to produce its effect, the general toxic symptoms which it often causes, and its failure after all greatly to modify the actual pain of the operation.

Of the three general anæsthetics, nitrous oxide gas is suitable for short and rapid operations, but it is difficult of administration to a patient who is too young to follow the directions of the anæsthetist, and to those in whom the upper air passages are seriously obstructed. Chloroform is unquestionably dangerous, and, on the whole, not superior to ether. In the hands of a skilful anæsthetist and properly administered, ether will, as a rule, prove most satisfactory. Under deep anæsthesia the pharynx is completely relaxed and ample time is afforded for all the care and thoroughness necessary, the patient meanwhile being free from pain. The theoretical objections that ether is dangerous, that the children are apt to be injured by it, and that its action increases the amount of bleeding at the time of the operation, are not true. If more blood flows with anæsthesia than without, it is largely because under the former condition a much greater amount of tissue is removed.

Much caution should be employed in the after-care of the patient. He should not be at once dismissed, but should be put to bed, and kept there for at least twenty-four hours, and until all signs of disturbance or shock have subsided. Attention to this detail will be amply repaid, for it lessens the possibility of bleeding, prevents infection, guards the patient against taking cold, and greatly reduces the general depression due to the slight shock of the operation.

Meanwhile the administration of tonic doses of iron and quinine will materially hasten recovery. In other words, to this surgical condition the ordinary rules of surgical treatment should be applied.

It must not be considered that with the performance of the operation the case is completed and all possible help to the patient afforded. The general condition should be made as perfect as possible, to which end change of air is often of great benefit, and, most important of all, the patient should be carefully examined in order to determine whether or not the operation has resulted in a thorough and complete success. Should the contrary prove to be the case, further treatment may be called for, and although when properly performed at first, it will seldom be necessary to repeat it, there is no reason why this should not be done when required. Indeed, it is well, in difficult cases, to mention to the parents beforehand the existence of such a possibility.

The pharynx being freed from the offending tissue, such conditions as catarrhal inflammation, relaxation of the uvula, and the general tendency to local congestion can be greatly benefited by topical treatment, although in most instances special interference will be unnecessary.

The second variety of treatment relates to the cure of certain direct results of the naso-pharyngeal obstruction, namely, to mouth breathing, to errors of pronunciation, and to deformities of the chest walls and of the framework of the nose.

When free nasal respiration has been actually established every possible encouragement should be held out to the patient to close the mouth and breathe through the nose, both while awake and when asleep.

The operation for the removal of hypertrophied adenoids is not so simple and easy as many suppose it to be. On the contrary, its successful performance requires knowledge, experience, and skill.

III. TONSIL OF THE TONGUE.

[Glandular (or adenoid) tissue at the base of the tongue.]

This tissue, the existence of which has long been known, is analogous to the structure of the faucial tonsils and of the tissue at the vault of the pharynx. It completes the circle of glandular tissue which surrounds the pharynx.

Histologically, the principal difference between the faucial tonsil and the lingual lymphoid masses is, that while in the tonsils the lymphoid tissue is collected together into a circumscribed and well-defined mass, the lymphoid tissue at the base of the tongue is disseminated in small groups over a considerable surface. Strictly speaking, these groups are not glands, since they have no excretory duct nor outlet, but are enclosed bodies and belong in reality to the lymphatic system. They are usually three or four lines in diameter, and are loosely embedded in the submucous tissue. Their hilus is covered with a thin mucous membrane. Their sac contains a varying number of follicles, closely resembling those of Peyer's glands of the intestines. The existence of the lingual tonsil, so-called, is a normal condition. The collections of tissue are located between the circumvallate papillæ and the epiglottis. Normally they are not conspicuous, nor is their presence manifest excepting upon irritation, when it will be discovered that the region which they occupy is highly sensitive, and liable to marked reflex phenomena.

In examining the base of the tongue with the laryngoscope there is found, normally, a free interval between the base of the tongue and the epiglottis. When the lymphoid tissue is hypertrophied, this interval is more or less filled up, and the tip of the epiglottis may be seen impinging against the tongue or, apparently, buried in a mass of enlarged and prominent glands. The hypertrophy may extend laterally, and thus shut off the view of the pyriform sinus. It is often more markedly developed upon one side than upon the other. The glands may be seen projecting backward, each one more or less distinct and by itself, and the whole forming an aggregation which is clearly more prominent and conspicuous than is seen in the natural state of the parts. Dilatation of the blood-vessels of the neighborhood is generally present. As to what constitutes the normal condition of the base of the tongue, it may be said that in the vast majority of cases pathological symptoms will be caused only by abnormal enlargement of the lymphoid tissue so pronounced that, when sought for, it can hardly fail of being recognized.

The disease commonly met with in the lingual tonsil is a condition of general hypertrophy, in which the whole gland is increased to double the normal size or more, and its follicles themselves are considerably enlarged. This hyperplasia is very similar to the condition seen in chronic hypertrophy of the faucial tonsil. Associated with the hypertrophy there is often a dilatation of the blood-vessels. Sometimes but one or two vessels may be enlarged and sometimes many of them. It is not uncommon to see it in children.

The causes of the hypertrophy are, to a great degree, identical with those of chronic hypertrophy of the faucial tonsils. They may depend upon disturbances of the circulation due to renal or hepatic disorders, or upon cardiac disease. Among them acid indigestion plays a particularly important part.

The symptoms observed in these cases are many and, as a rule, well marked. They are more commonly observed in women than in men, and are in general such as commonly accompany hyperæsthesia of the parts. Thus, the patient complains of a sensation of pricking, or of the presence of a foreign body in the throat. The pain is usually localized, but sometimes radiates to other parts, these subjective phenomena being increased if the tongue be drawn backward. The explanation of the symptoms is simple. Normally, the margin of the epiglottis is free. When the lymphoid tissue of the tongue is so enlarged as to come in contact with it, then, two parts being in contact which usually do not touch each other, the subjective sensation of a foreign body results, accompanied or not by pain in proportion to the amount of irritation produced. Patients occasionally complain of pain shooting up to the ears, or refer their discomfort to the stomach, larynx, trachea, or intrascapular region. Pain is also present when the glands are in a state of subacute inflammation.

The effect of hypertrophy of the lingual tonsil upon the voice is marked and disastrous, for fatigue in speaking and singing is a common symptom. When the trouble is not severe the only complaint may be that the patient has pain while talking, without being hoarse, the neighboring parts of the throat being normal. In some cases the vocal fatigue can be traced to deficient innervation. In cases in which the difficulty is more pronounced, the voice may be entirely lost. In some cases the voice is uncertain, being sometimes good and sometimes poor. Sometimes it is unreliable or difficult to control, breaking during the effort to sing. Again, there may be a marked tendency to sing out of tune, and the timbre of the voice may be seriously impaired. In other cases the normal range of the voice is interfered with, the patient not being able to produce two or even three of the highest notes of which his voice is capable.

Some patients suffer from cough, which is observed in two different forms. It is either violent, spasmodic, and almost incessant, or of a hacking character, appearing at shorter or longer intervals. The spasmodic form, as a rule, occurs when the hypertrophied glands encroach upon the epiglottis, and is less frequent than the hacking cough. The latter often gives rise to great anxiety, as the patient fears it to be a symptom of developing pulmonary phthisis. This form of cough is often present when there is merely contact between the glands and the epiglottis, and it is probably due to the friction of the tongue and epiglottis against each other during their movements.

It is a question whether the so-called "globus hystericus," as seen in nervous women, is not often less a matter of the imagination than has been commonly supposed. In patients afflicted with this complaint, hypertrophy of the lingual tonsil has frequently been observed, while in patients of nervous temperament other reflex symptoms of the condition are often severe. On the other hand, the globus hystericus has been seen in patients in whom the base of the tongue was practically normal.

Finally, attacks of dyspnœa resembling asthma may occur in patients with enlarged lingual glands.

The prognosis is good, but the length of time required to effect a cure is not always easily determined.

Too radical measures for the relief of this condition are not indicated, and much harm has been done by the free use of surgical methods in cases in which simpler means would have answered the purpose. Thus, in cases depending upon hyperacidity of the stomach, correction of the indigestion will cure the tongue. When Bright's disease is present, or when there is disease of the liver or of the heart, the attempted removal of the enlargements or the obliteration of the dilated vessels can only result in harm.

In the congestive form of enlargement, especially when dependent upon indigestion, relief is often afforded by cleansing and astringent applications made to the base of the tongue by means of a good spray atomizer, attention being paid meanwhile to the constipation, or to the hyperacidity of the stomach, which may be present.

When the hypertrophic masses are permanent, requiring actual removal, surgical means are called for. Many special methods have been suggested for this purpose, from the use of various escharotics to actual ablation by means of cutting instruments. The latter are in general not to be preferred. On the whole, the most satisfactory means seems to be either the galvano-cautery applied by means of a flat electrode, the galvano-caustic snare, or the cold-wire snare. Under cocaine anæsthesia the operation is usually not very painful, and healing takes place in a few days.

Suppurative inflammation of the lingual tonsil is rare. When it is present it is necessary to determine the precise location of the lesion, and to remember that such attacks are sometimes accompanied by œdema of the larynx. Evacuation of the abscess during sleep may prove dangerous. Chronic abscess of this region and retention cysts have been observed. This condition is sometimes so severe as to suggest Ludwig's angina.

TOPEKA MINERAL WELLS.—Shawnee County, Kansas.

Post-Office.—Topeka. Hotel.

These wells, two in number, are located on Harrison Street, in the city of Topeka. We are informed that a good hotel has been established at the wells for the accommodation of persons requiring treatment. Turkish, Russian, electric, and steam baths may be obtained. The following analysis of the water was made by Messrs. Barnes and Sim, chemists. The estimate was presumably made in grains per United States gallon.

One United States gallon contains (solids): Magnesium chloride, gr. 11.76; sodium sulphate, gr. 19.26; magnesium sulphate, gr. 14.36; sodium nitrate, gr. 1.94; sodium bicarbonate, gr. 35.61; calcium bicarbonate, gr. 22.48; iron bicarbonate, gr. 28.06; ammonium sulphate, gr. 1.50; alumina, gr. 0.40; silica, gr. 10.28; organic matter, gr. 1.76; phosphoric acid, a trace. Total, 147.35 grains.

The baths have been in operation since 1879. They are highly recommended for obstinate cases of rheumatism. The water is also used commercially. The analysis shows a fairly strong saline-purgative water, and it should be useful in cases to which such waters are applicable.

TORMENTIL. See "*Rosaceæ*," under the heading *Roses*.

TORONTO, CANADA.—This city, of about 250,000 inhabitants, the metropolis of the Province of Ontario, is situated in lat. 43° 39' N., and long. 79° 23' W., on the northwestern shore of Lake Ontario. Meteorological observations made here can be taken to illustrate the special climatic features of the northern shores of Lake Ontario, known as that of the "Lower Lake Region." For the following description of the topography of this region, as well as of the city, the writer is indebted to Dr. P. H. Bryce, Secretary of the Ontario Board of Health.

"Lake Ontario is 240 feet above the sea level and lies in a depression produced by glacial erosion, being surrounded by five well-marked lake beaches, extending from the Oak Ridges escarpment on the north, to the Catskills to the south. Northwesterly, these heights form a central plateau stretching to Lake Huron, with a general elevation of 1,000 to 1,300 feet, thereby protecting the Lake Ontario region from the severe storms which move from the northwest plains over the upper lakes, and spend their force on the northwest slopes of the plateau as rain and snow storms. The annual rainfall of Toronto averages 31 inches, with usually a light snowfall. The soil underlying the city and neighboring shores of the lake is a tenacious Post-glacial clay—the Erie clays, geologically—capped, however, in the upper portions of the city with sands and gravels. The combined system of sewerage has converted Toronto from what was "Muddy York" to a paved city, famed equally for its well-kept streets and lanes and for its wealth of residential streets lined with forest shade trees, and its splendid central and suburban parks, with magnificent deep ravines, whose precipitous sides form valleys eroded through the clays by the Humber and Don rivers. Lying in front of the city is an island, which, when the city was founded, was a peninsula formed from the weather-worn cliffs of Scarboro Heights in the east, reposited as a sandbar five miles in length, which bounds a bay some two miles in width in front of the city. This island now forms the summer home of thousands of city dwellers, and on it there is also a lakeside park, visited daily by many thousands. In the midst of the lake, a mile beyond the island, and fully protected against the sewage which is poured into the bay, is the intake of the city water pipe. The breezes blowing over the deep waters, the temperature of which in even late summer seldom rises above 50° F., maintain a coolness which is typical of the whole northern shores of the lake, and which has caused these shores, from Hamilton to Kingston, to become yearly more and more the summer home of many thousands, especially from the Middle and the Southern States.

"The great depth of the lake keeps the waters open all winter, and gives to the climate of the surrounding region, during the winter and early spring, an unpleasant dampness and coldness similar to that which prevails in northern marine climates. The following table will enable the reader to compare the climatic conditions of Toronto with those of several other places where meteorological records have been kept."

ince of Ontario is between 30 and 40 inches. At Toronto the annual percentage of bright sunshine is 44, and for July at the same place it is 60. This is much higher than in England, for instance, where it is about 36, according to Stupart. The relative humidity, 77 per cent. for the year, indicates a moderately damp atmosphere.

As the metropolis, for over a hundred years, of the province, Toronto is adorned with a fine House of Parliament, a splendid City Hall, and a Provincial University, with lands set apart for educational purposes, in the first years of the province, and throughout which are distributed some ten colleges, which cluster around University College, probably the finest type of gothic architecture in America. Some three thousand students are enrolled in those colleges. There are, in addition, three

MEAN TEMPERATURES AND HUMIDITY.

Place.	Latitude.	Height in feet.	February.				July.				Relative Humidity.	
			Mean max.	Mean min.	Extreme max.	Extreme min.	Mean max.	Mean min.	Extreme max.	Extreme min.	February.	July.
Toronto	43° 39′	350	30.8°	18.2°	44.0°	1.0°	81.4°	63.5°	93.3°	53.3°	80	74
New York	39 57	185	39.9	23.8	55.0	3.0	85.5	63.6	90.0	55.0	77	70
Boston	42 21	125	37.1	11.5	56.0	− 4.0	77.4	60.1	89.0	51.0	71	68
Chicago	41 52	715	30.9	14.2	47.0	−18.0	80.7	64.6	94.0	56.0	76	68
Ottawa	45 26	330	26.1	8.5	40.0	−12.0	82.2	62.5	97.2	55.2	81	74
Winnipeg	49 53	760	13.3	11.4	41.0	−32.2	79.0	56.8	88.5	47.0	94	74
Calgary	51 2	3,389	24.9	7.0	40.3	9.7	72.4	46.0	86.3	39.0	73	61
Kamloops	50 41	1,193	35.5	22.0	44.6	11.5	78.9	54.8	98.0	46.0	79	67
Gravenhurst	44 50	770	25.0	8.8	40.0	−22.2	82.5	60.6	97.0	52.0	75	76

The table is interesting as showing that, while the relative humidity in winter is high, its mean minimum temperature in February is higher than it is either in Boston or in Chicago, though lower than in New York. On the other hand, its maximum mean is the same. Its two summer means are practically those of Chicago, although it is higher in both than it is in Boston.

The annexed chart, obtained through the kindness of Prof. R. F. Stupart, director of the Meteorological Service, Toronto, will show in detail the characteristic climatic condition of Toronto, and will also serve to illustrate the climate of the lower lake region. It will be observed that the winters are not excessively cold or the summers oppressively hot, this being due, as Professor Stupart remarks, to the tempering influence of the lakes. In May the mean temperature of the whole Ontario peninsula, says the same authority, is slightly higher than for the south of England. September and October are "generally delightful months." Much snow falls during the winter, but it seldom remains on the ground until March. The annual precipitation of the entire prov-

medical colleges, which have a four years' curriculum of study, with a fifth year of clinical work before a license to practise is given.

Toronto is naturally the centre of the larger charities in the province; all hospitals, refuges, and reformatories are located here under governmental supervision. There are seven large hospitals, general and special, with provision for 6,000 patients annually, and twelve homes and refuges provided for 1,000 inmates. It is thus apparent that the 400 physicians of the city, as well as the students of the colleges, have ample opportunities for developing medical practice into a high state of efficiency.

"DEATHS FROM CONTAGIOUS DISEASES IN TORONTO IN 1901.

the healthfulness of the city, with all the already mentioned charities centred in it, is illustrated by the fact that in 1901, the year of the last Canada census, the mortality was as follows: Toronto: Deaths per 1,000 population in 1901, 16.5; New York: Deaths per 1,000 population in 1900, 20.4."

One hundred and fifteen miles north of Toronto, near the town of Gravenhurst, is situated the Muskoka Cottage Sanatorium for the treatment of incipient cases of pulmonary tuberculosis. This institution is located in a beautifully wooded, sheltered park of some 80 acres, on the shores of Lake Muskoka. It has an altitude of about 800 feet, in the region known as the Highlands of Ontario.

The climate is a bracing one, and the air is dry and free from dust. The soil is dry, and of rocky formation, and the water very soft. The winters are cold, but there are no sudden changes of temperature. Snow remains on the ground from December to March. There is a very considerable amount of sunshine. The patients can remain out of doors from six to eight hours throughout the winter.

The buildings are constructed upon the cottage plan, with an administration building in the centre of the group. Each patient has a separate room, and the use of the sun parlors and piazzas. The accommodations at present allow for fifty patients, but the number of the cottages is to be increased.

Walking, sleighing, snowshoeing, and, in the summer, boating on the lake, are permitted for suitable cases. The cost to each patient is six dollars per week. The results so far have been satisfactory. This region also affords relief to those suffering from asthma and hay fever, and is much frequented as a summer resort by the people from the cities and towns farther south.

[For an excellent account of the climate of Canada as a whole the reader is referred to the paper of Professor Stupart, read at the meeting of the British Association, Toronto, 1897, and reprinted from the *Scottish Geographical Magazine* for February, 1888.] *Edward O. Otis.*

TORTICOLLIS.—(Synonym: Wry-neck.) Torticollis, as the name indicates, is a twisted neck, a distortion caused in most cases by active contraction or by actual shortening of one or more of the lateral muscles that control the head. Similar distortion may be present in Pott's disease, but in this instance the deformity is a symptom of a more important disease, while the term torticollis implies simple deformity.

Torticollis may be divided into two classes—the congenital and the acquired.

CONGENITAL TORTICOLLIS is a painless shortening of the tissues of one side of the neck of intra-uterine origin. Acquired torticollis is almost always accompanied at its onset by discomfort or pain. This afterward subsides, leaving the deformity; thus torticollis, from a therapeutic standpoint, may be divided into the acute and the chronic forms.

Whatever may have been the cause of the deformity, the sterno-mastoid muscle is most often affected, and typical torticollis implies contraction or shortening of this muscle. As an effect, therefore, the chin is slightly elevated and turned away from the contraction. The head is tilted toward the shortened muscle, and as a whole is displaced toward the opposite shoulder. There are also irregular forms of torticollis due to contraction of other muscular groups, to which attention will be called later.

Torticollis is a comparatively uncommon deformity, and the acquired form is far more common than the congenital variety. The sexes are about equally affected, and one side as often as the other.

CONGENITAL TORTICOLLIS.—In most instances the deformity is slight at birth, and it does not attract attention until the child is able to support the head, and in many cases not until a much later period. In exceptional instances, however, the deformity is well marked at birth and is accompanied by noticeable asymmetry of the head and skull. In cases of this character the contraction often involves all the lateral tissues of the neck, indicating that its cause must have been a fixed or constrained position in utero, an explanation that may be applied to the great majority of the milder cases also.

It may be stated in this connection that it was at one time generally taught that so-called congenital torticollis

FIG. 4738.—Well-marked Congenital Torticollis of the Left Side, showing the Effect of the Contraction in Displacing the Head toward the Opposite Shoulder.

was due to injury at birth, the sequence of events being somewhat as follows: The sterno-mastoid muscle was ruptured; rupture was followed by hemorrhage into the substance of the muscle, which in turn set up inflammation; this was followed by scar contraction and by deformity. This theory has now few supporters, for the following reasons: In the majority of cases of true congenital torticollis discovered in early infancy, there is no evidence of hæmatoma. Hæmatoma is in but few instances followed by torticollis, nor is rupture of muscle in later life or in other situations followed by such shortening. It is apparent, of course, that a congenitally short muscle might be injured at birth with a resulting hæmatoma, also that injury at birth might induce irritation or discomfort, and that deformity might follow the habitual attitude assumed by the patient for the relief of this discomfort.

Pathology.—In the ordinary type of congenital torticollis, as demonstrated at operations on children, the substance of the affected muscle or muscles is simply lessened in amount, and there is a disproportionate area of tendinous substance, as contrasted with the contractile tissue. In other instances the muscle may be traversed by fibrous bands or patches of scar-like tissue. Such changes are far more common in acquired torticollis, and they indicate primary or secondary inflammation of the muscular substance. In cases of torticollis in infancy, or when the distortion is slight, there is but little general effect of the local contraction; but, if the deformity persists, secondary changes appear. The face on the affected side is flatter, the nose, the corner of the mouth, and the eyelids may be drawn down toward the contraction, and the skull even may be markedly deformed. There is in all cases of this character lateral distortion of the cervical spine, the convexity being on the side opposite the contraction. Later, secondary curvature of the spine develops. Usually, there are also an increase of the dorsal convexity, "round shoulders," and a lateral compensatory curve in the direction opposed to the superior deformity.

If the deformity persists the neighboring muscles become eventually involved, together with the other tissues on the contracted side, the fascia presenting the greatest resistance to the correction.

Non-Operative Treatment of Congenital Torticollis.—If the deformity is discovered in early infancy it may be overcome, in many instances, by massage and stretching. In this manipulation one person holds the arm firmly, and another draws the head in the opposite direction, meanwhile vigorously massaging the contracted tissues. This treatment is carried out twice daily for about ten minutes each time. In holding the child and arranging the pillow during sleep, one should take advantage of postures that oppose the deformity.

Hæmatoma.—As has been stated, hæmatoma is not unusual after difficult labor. It forms a hard, resistant, ovoid swelling in the substance of the sterno-mastoid muscle. It is usually discovered about the second week after birth. Its absorption may be hastened by massage with some bland ointment. If there is a tendency toward contraction or toward a posture that might favor deformity, this should be prevented by manipulation and by posture.

Operative Treatment.—If the muscle or muscles are actually shortened, and if deformity cannot be overcome by manipulation in the manner described, operative treatment is indicated. This statement applies to practically all forms of torticollis, whether congenital or acquired, in which the deformity is persistent. The treatment of acute torticollis, and the prevention of deformity will be described later. The object of operative treatment is

FIG. 4739.—The Method of Applying the Plaster Bandage after Operation on the Left Side, to Hold the Head in the Attitude of Overcorrection. (From Whitman's "Orthopedic Surgery.")

to overcorrect the deformity and to hold the head in the overcorrected position until the parts are thoroughly adjusted to their new relations.

Forcible Correction.—The patient having been anæsthetized the shoulders are elevated upon a hard pillow, the arm is then held firmly by an assistant, and the operator begins a series of forcible movements, alternately stretching and relaxing the contracted parts and forcibly massaging them with the ulnar border of the hand. If the shortened muscles are very resistant, it is well to divide the tendinous insertions subcutaneously as a preliminary measure. In this operation the tendon being grasped between the thumb and finger, it may be divided without fear of injuring the deeper parts. One then proceeds with the forcible manipulation until all resistance has been overcome, and until the lateral curvature in the cervical region has entirely disappeared. The head is then fixed in the attitude of extreme overcorrection by means of a plaster bandage. This should include the upper part of the chest and shoulders, circular turns being made about the head. It should remain in position for at least three weeks, and for a much longer time if the appliance is comfortable, and if it is not considered objectionable. After removal of the supporting bandage the head should be turned forcibly from time to time into the attitude of overcorrection, for the purpose of preventing recurrence of deformity; and systematic exercises should be employed to strengthen the muscles and to re-establish the normal poise.

The Open Operation.—In many instances, and especially in cases of long standing in older subjects, the open operation is to be preferred to tenotomy and forcible stretching. An incision, parallel to the sterno-mastoid muscle and half-way between its two insertions, is made, running upward from the clavicle about an inch and a half. Through this incision all the resistant bands are divided as they appear under tension. When all resistance to overcorrection has been removed, forcible manipulation is carried out and the head is fixed in the manner already described. This fixation is not always necessary in the treatment of older subjects.

It should be stated that when the deformity is of long standing, it may be impracticable to fix the head at first in the overcorrected position, because of the impairment of the circulation or because of the discomfort that it causes.

ACQUIRED TORTICOLLIS.—As has been stated, acquired torticollis is far more common than the congenital form. At least eighty per cent. of the cases begin during the first ten years of life.

The deformity may be divided into two main groups, the common form or so-called acute torticollis and the irregular forms.

Acute torticollis is a painful contraction secondary to injury or disease of the muscles, or to irritation of the peripheral nerves. As a rule, the sterno-mastoid and trapezius muscles are involved, but occasionally other muscular groups are affected. A common form of torticollis is the so-called rheumatic or stiff neck, in which the muscles of the neck are stiff and sensitive to pressure; this form hardly requires consideration.

By far the most important form of acute torticollis is that which often follows irritation of the peripheral nerves in the naso-pharynx or its neighborhood; thus it is often a sequel of tonsillitis, measles, diphtheria, and the like. It may be preceded by toothache or earache, and it is often accompanied by enlarged or suppurating cervical glands. The onset of the affection is gradual, often preceded by fever, and the head gradually assumes the characteristic attitude of torticollis, and is fixed by the tonic contraction of the affected muscles. Attempts to overcome the deformity cause great pain, as do unguarded movements. It is particularly difficult to place the head in a comfortable position when the child lies down; thus "getting the child to bed" is a troublesome task.

The patients often become extremely nervous, and it would appear that the affection is more common among children of the nervous type. As has been stated, the deformity is usually typical, the muscles affected being the trapezius and the sterno-mastoid. In rare instances the contraction may affect both sterno-mastoid muscles, so that the head is drawn forward and downward between the shoulders; or the posterior muscles may be involved and the head is drawn backward, so-called posterior torticollis. The muscles and other tissues become shortened. The pain and discomfort finally disappear and the case becomes one of chronic torticollis, although in the milder forms spontaneous recovery is possible.

Treatment.—The treatment is symptomatic and preventive. Support is always indicated. As an immediate application the neck may be enveloped in a heavy muff-like collar of cotton; this should reach from the shoulders to the ears, and should be of such thickness as actually to support the head. It is held in position by circular bandages, and it may be stiffened by layers of adhesive plaster. This provides heat and fixation, and for the early cases it is often an efficacious remedy.

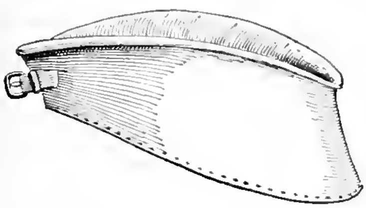

FIG. 4740.—The Thomas Collar. This apparatus is of service in the treatment of the milder cases of acute torticollis.

In most instances a more comprehensive support is indicated. Such a support is afforded by the plaster jacket and the jury mast; the elastic tension of the halter, if properly applied, will eventually overcome the spasm, and in great degree at least correct the deformity. This correction is further assisted by massage and by gentle manipulation of the head. When the spasm and deformity have been overcome, exercises to restore the ability of the weakened muscles may be employed. This treatment is particularly efficacious in those cases in which the muscular substance is involved by suppurating cervical glands. The duration of the treatment may be from several weeks to several months. If the deformity has persisted for more than six months operative treatment after the method described is, as a rule, indicated. It is evident, of course, that if acute torticollis is of secondary origin all sources of possible irritation should be looked for and treated if found; also that the general condition of the patient should receive attention.

IRREGULAR FORMS OF TORTICOLLIS.—*Spasmodic Torticollis.*—This is a form of convulsive spasm of the muscles of the neck resembling somewhat in its general characteristics writer's cramp. It is essentially an affection of adult life and is more common in individuals of a neurotic type. The onset is usually gradual, the first indications being sensations of stiffness and discomfort, drawing sensations, and twitchings of the head. When the affection is established there are at intervals spasmodic contractions of the affected muscles, which draw the head with a jerking motion into the attitude of extreme deformity. The spasm then relaxes, to recur at frequent intervals. These contractions may be painless, but in many instances the sensation is cramp-like. After a time deformity persists, the affected muscles becoming hypertrophied and structurally shortened.

Etiology.—Little is known of the etiology. Many of the patients present a neurotic family or personal history, and in certain instances constant or constrained attitudes in occupation, defective eyesight, and the like apparently induce the affection. There is little tendency toward spontaneous recovery.

Treatment.—The general condition of the patient should receive attention, and predisposing causes, such as occupation, should be avoided if possible. In mild cases massage, systematic exercise, and in some instances support in the form of a collar or light metallic brace may be of service. In confirmed cases resection of the nerves that supply the affected muscles seems to be the most effective remedy.

If the spasm is confined to the sterno-mastoid and trapezius muscles removal of a portion of the spinal accessory nerve may be sufficient. An incision is made along the anterior border of the sterno-mastoid muscle from the mastoid process to a point about one inch beyond the angle of the jaw. One then exposes by blunt dissection the transverse process of the atlas, which lies directly below the mastoid process. This is a valuable landmark because the spinal accessory nerve usually passes directly over it, or slightly in front of its most prominent part. Traction on the muscle will usually make the nerve prominent. If it is not readily found its position may be ascertained by drawing the finger nail across the bottom of the wound, a sharp contraction following pressure on the nerve. This having been isolated, a section, at least an inch long, should be removed. If the sterno-mastoid muscle is actually shortened, it should be divided and a portion of the trapezius also, if this resists the correction of the deformity. Fixation of the head is, as a rule, not required after the operation. In many instances the muscular spasm involves the other muscles of the neck. In such cases resection of the posterior branches of the upper cervical nerves, in addition to the complete division of the contracted parts, may be required.

In the ordinary operation an incision, about three inches in length, is carried downward from the occiput, parallel to and about one inch from the spinous processes. It is continued through the trapezius and complexus muscles, exposing the posterior branches of the nerves. Those of the three upper nerves are then resected. As has been stated, complete division of the muscles that are shortened accompanies the operation.

OTHER FORMS OF IRREGULAR TORTICOLLIS.—*Paralytic Torticollis.*—One or more of the muscles of the neck may be paralyzed, most often the result of an extensive anterior poliomyelitis. Isolated paralysis of the muscles is uncommon.

Diphtheritic Torticollis.—Paralysis of muscles may be a sequel of diphtheria, the trapezii muscles being most often involved. This allows a forward droop of the head. The diagnosis is usually apparent.

Posterior Torticollis.—The most common form of posterior torticollis is the so-called cervical opisthotonos which is often a symptom of cerebro-spinal or basilar meningitis. A slight degree of the same deformity is not uncommon in ill-nourished infants.

Rachitic Torticollis.—In the progressive stage of rachitis, in which the characteristic kyphosis is present in the lower part of the spine, the head may be tilted backward in compensation. Occasionally the attitude may be increased by slight spasm of the posterior muscle.

Ocular Torticollis.—In rare instances the head may be carried habitually in an attitude of lateral distortion to accommodate defective vision. This is, however, rather an improper attitude than a symptom of torticollis. The treatment of these uncommon and as a rule unimportant varieties of deformity does not require especial consideration.

TOXINS, TOXALBUMINS.—Toxins are poisonous synthetical products of bacterial growth.

The exact composition of toxins has not as yet been discovered, but it is believed that they are of proteid character. At first all the toxins were supposed to be albumins, but recently some of the most important, such as those produced by the tetanus and diphtheria bacilli, have been shown to possess characteristics which separate them from that class. Toxins are formed during the growth of bacteria in media containing no proteid, but more abundantly when it is present. Toxins are divided into extracellular and intracellular poisons. Thus, the toxins produced by the diphtheria and tetanus bacilli during their growth in the tissues or culture media are largely given up to the culture fluid, but little remaining in the bacterial protoplasm, while the toxins elaborated by the typhoid, tubercle, glanders, and colon bacilli, and indeed by the majority of parasitic and saprophytic bacteria, are largely retained in the bodies of the bacteria until their death and destruction.

Among the properties of the extracellular toxins are the following: They are so far as known uncrystallizable, and thus differ from ptomaïns; they are soluble in water and they are dialyzable; they are precipitated along with proteids by concentrated alcohol, and also by ammonium sulphate; if they are proteids they are either albumoses or allied to the albumoses; they are relatively unstable, having their toxicity diminished or destroyed by heat (the degree of heat, etc., which is destructive varies much in different cases). Their potency is often altered in the precipitations practised to obtain them in a pure or concentrated condition, but among the precipitants ammonium sulphate has little if any harmful effect. Regarding the intracellular toxins which are more intimately associated with the bacterial cell we know much less, but it is probable that their nature is similar, though some of them at least are not so easily injured by heat, *e.g.*, in the case of the product of tubercle bacilli. In the case of all toxins the fatal dose for an animal varies directly with the species, body weight, age, and previous conditions as to, *e.g.*, food, temperature, etc. In estimating the minimal lethal dose of a toxin these factors must be carefully considered.

The following is the method usually employed for obtaining concentrated extracellular toxins. The toxic fluid is placed in a shallow dish, and ammonium sulphate crystals are well stirred in till no more dissolve. Fresh crystals to form a bulk nearly equal to that of the whole fluid are added, and the dish is set in an incubator at 37° C. (98.6° F.) over night. Next day a brown scum of precipitate will be found floating on the surface. This contains the toxin. It is skimmed off with a spoon, placed in watch-glasses, and these are dried in vacuo and stored in the dark, also in vacuo, or in an exsiccator containing strong sulphuric acid. For use, the contents of one are dissolved up in a little normal saline solution.

The comparison of the action of bacteria in the tissues in the production of these toxins to what takes place in the gastric digestion has raised the question of the possibility of the elaboration by these bacteria of ferments by which the process may be started. It would not be prudent to dogmatize as to whether the toxins do or do not belong to such an ill-defined group of substances as the ferments. It may be pointed out, however, that the essential concept of a ferment is that of a body which can originate change without itself being changed, and no evidence has been adduced that toxins fulfil this condition. Another property of ferments is that, so long as the products of fermentation are removed, the action of a given amount of ferment is indefinite. Again, in the case of toxins no evidence of such an occurrence has been found. A certain amount of a toxin is always associated with a given amount of disease effect, though a process of elimination of waste products must be all the time going on in the animal's body. Again, too much importance must not be attached to loss of toxicity by toxins at relatively low temperatures. Many proteids show a tendency to change at such temperatures; for instance, if egg albumen be kept long enough at 55° C. nearly the whole of it will be coagulated. Such considerations suggest that the relation of toxic action to fermentation must be left an open question.

Similar Vegetable and Animal Poisons.—Within recent years it has been found that the bacterial poisons belong to a group of toxic bodies all presenting very similar properties, other members of which occur widely in the vegetable and animal kingdoms. Among plants the best-known examples are the ricin and abrin poisons, obtained by making watery emulsions of the seeds of the Ricinus communis and the Abrus precatorius (jequirity) respectively. The chemical reactions of ricin and abrin correspond to those of the bacterial toxins. They are soluble in water, they are precipitable in alcohol, but being less easily dialyzable than the albumoses they have been called toxalbumins. Their toxicity is seriously impaired by boiling, and they also gradually become less toxic on being kept. Both are among the most powerful poisons known, ricin being the more fatal.

It is also certain that the poisons of scorpions and of poisonous snakes belong to the same group. The poisons derived from the latter are usually called venins, and a very representative group of such venins derived from different species has been studied. To speak generally, there is derivable from the natural secretions of the poison glands a series of venins which have all the reactions of the bodies previously considered. Like ricin and abrin, they are not so easily dialyzable as bacterial toxins, and therefore they have also been classed as toxalbumins. While up to the present we have not been able to discover the exact chemical composition of any toxin, or even to obtain it in a pure state, many interesting facts upon the nature of toxins have been discovered by physiological methods.

From a large number of most carefully conducted experiments with the toxin and antitoxin of diphtheria, Ehrlich has formulated a theory concerning the constitution of the former. This theory has undergone several modifications since it was first proposed, and it is difficult to give an exact statement of it as it now stands. However, we will attempt to state in condensed form its essential points as follows:

Toxins and antitoxins neutralize one another after the manner of chemical reagents. The chief reasons for this belief lie in the observed facts: (*a*) that neutralization takes place more rapidly in concentrated than in dilute solutions; and (*b*) that warmth hastens and cold retards neutralization. From these observations Ehrlich concludes that toxins and antitoxins act as chemical reagents do in the formation of double salts. A molecule of the poison requires an exact and constant quantity of the antitoxin in order to produce a neutral or harmless substance. This implies that a specific atomic group in the toxin molecule combines with a certain atomic group in the antitoxin molecule.

The toxins, however, are not simple bodies, but easily split into other substances which differ from one another in the avidity with which they combine with antitoxin.

These derivatives Ehrlich calls prototoxins, deuterotoxins, and tritotoxins.

All forms of toxins are supposed to consist of two modifications, which combine in an equally energetic manner with antitoxin or with suitable receptors in the cells, but differ in their resistance to heat and other destructive agents.

The less resistant form passes readily into a toxoid substance which has the same affinity for the antitoxin or the cell receptors as the original toxin, but is not poisonous. The facts observed, Ehrlich thinks, are best explained on the supposition that the toxic molecule contains two independent groups of atoms, one of which may be designated as the haptophorous and the other as the toxophorous group. It is by the action of the haptophorous group that toxin unites with antitoxin or the sensitive cell molecule.

The toxophorous group is unstable, but after its destruction the molecule still unites with the antitoxin or the sensitive molecule through its retained haptophorous group.

Specific antitoxins can be produced not only with toxins but with toxoids.

Bordet believes, in contradistinction to Ehrlich, that toxin unites in different multiples with antitoxin, so that the toxin molecule may have its affinities slightly, partly, or wholly satisfied by antitoxin. Slightly satisfied, it is still feebly toxic; combined with a larger amount of antitoxin it is not toxic, but still may, when absorbed into the system, lead to the production of antitoxin. Fully saturated, it has no poisonous properties and no ability to stimulate the production of antitoxin.

The most important of the extracellular toxins are those produced by the diphtheria and tetanus bacilli. These are very powerful, 0.0000001 gm. of the dried filtrate of a tetanus culture will frequently kill a white mouse, while one-tenth of that amount of dried diphtheria filtrate has killed a guinea-pig.

According to Madsen and Ehrlich the specific tetanus poison consists of two toxins, tetanospasmin and tetanolysin. To the first of these the tetanic convulsions are due, while the second has a hæmolytic action.

When the tetanus toxins are placed in the blood tetanolysin largely combines with the blood, while the tetanospasmin combines with the nerve cells. Each of these substances produces in animals a specific antitoxin. To obtain diphtheria and tetanus toxins for injection in animals the bacilli are grown in slightly alkaline beef broth for from seven to ten days. The broth is then filtered and preserved. Tetanus toxin is produced under anaërobic conditions, diphtheria toxin under free access of oxygen.

The bacterial poisons which reside in the bodies of the bacteria are mostly extracted only after the death of the organisms. Here in the invaded animal the disease effects are more closely associated with the actual presence of the bacteria in the vicinity than in the case of the extracellular toxins. Antitoxic sera, prepared from injecting animals with the filtrates of these bacteria, do not produce marked immunity in injected animals to infection with the living bacteria.

Tuberculin and mallein are mixtures of the bacterial poisons produced by the tubercle and glanders bacilli. Tuberculin is prepared from a fully developed culture of tubercle bacilli grown on meat broth containing five per cent. of glycerin. This is evaporated to one-tenth of its volume over a steam bath. Injected into tuberculous animals it causes a marked reaction in the infected tissue with constitutional disturbances and a rise of temperature.

Mallein is prepared in the same way from old cultures of the glanders bacillus. Injected into animals infected with glanders, it causes swelling and heat in the healthy tissues into which the mallein has been injected. Marked general disturbance and a rise of temperature of 3° to 5° F. usually follow. Typhoid, dysentery, colon, and many other bacilli and cocci contain intracellular toxins.

William H. Park.

TRACHEOTOMY.—(*Bronchotomy, Laryngotomy, Thyrotomy*, etc.) The term tracheotomy is used in general to signify an opening made from without into the windpipe in any part of its course. The term bronchotomy, originally and more properly used in this sense, has gradually fallen into disuse, and is now rarely met with. The term tracheotomy, in its exact sense, is applicable only to an opening made into the trachea proper; while thyrotomy, cricotomy, and laryngotomy, singly or in combination, may be used to describe openings made into the larynx only, and laryngo-tracheotomy and cricotracheotomy those involving both larynx and trachea.

Indications.—The object of a tracheotomy may be either to furnish a new aperture for the respiratory current, when the natural one is no longer sufficient, or to afford access to the interior of the tracheal canal for local therapeutic purposes, or for the removal of foreign bodies lodged within it. In these cases it is a remedial measure. In addition, it may be indicated also as a preventive measure, as a preliminary to some surgical operations involving the cavity of the nose, pharynx, or larynx, to render possible tamponade of the larynx, and to facilitate the administration of anæsthetics.

Any affection, laryngeal or supralaryngeal, which is causing or threatening asphyxia, is an indication for remedial tracheotomy. These conditions may be classified into: (1) Traumatic conditions; (2) inflammatory conditions; (3) neuroses; (4) neoplasms.

Some consideration of each of these classes is necessary:

I. Traumatic Conditions.—The first under this head come *wounds of the larynx*. When, as the result of such a wound, blood is flowing abundantly into the trachea, and hæmostasis by ordinary means cannot readily and speedily be accomplished; also, when the wound has partially severed the epiglottis so that it falls upon and occludes the glottic orifice—in these cases immediate opening of the trachea is imperative. Tracheotomy may also become necessary later in the history of a wound of the larynx in consequence of infiltration of the submucous laryngeal connective tissue, and of the epiglottic folds, by blood, serum, pus, or air, causing the symptoms of œdema glottidis. Glottic emphysema, demanding tracheotomy, may be caused by extension of a general emphysema of the neck, when inadequate means to relieve such emphysema have been employed, but it is more frequently a localized air infiltration of the aryteno-epiglottic folds from a penetrating wound of the larynx with contracted external opening. Local scarifications of the tumefied tissues, whether caused by fluid or by air infiltration, practised through the mouth, may suffice to afford relief in some cases, when time and opportunity can be had for them; but in all cases in which the suffocative symptoms are urgent or the conditions are not favorable for making such local scarifications, immediate tracheotomy should be done. In these cases it would also be justifiable for a person provided with the necessary instruments, and skilled in their use, to try intubation after the method of O'Dwyer.

Burns of the larynx and pharynx, the result of swallowing hot fluids or caustic agents, or of the inhalation of steam, are liable to be followed by œdema sufficiently great to require tracheotomy.

Fractures of the larynx are likely to involve conditions making tracheotomy necessary. Displacement of the cartilages may in itself produce sufficient occlusion to become an indication. Consecutive œdema may result, as in the case of incised and punctured wounds of the larynx above considered; phlegmonous purulent infiltration is likely to develop; blood infiltrations are to be expected; in some instances paralysis of the glottic dilators, from injury to the laryngeal nerves or their compression by displaced cartilages or inflammatory effusions, may supervene—any of these conditions indicate tracheotomy.

Cicatricial contractions may result from loss of substance attending any of the above-mentioned traumatisms of the larynx, and may produce stenosis of a high degree. More or less occlusion may also result from adhesions between soft parts following the cicatrization of wounds of the larynx or trachea, and from the healing in abnormal situations of displaced cartilaginous fragments or flaps of soft tissue. In either of these conditions tracheotomy is indicated as soon as any considerable embarrassment in breathing is experienced; it serves both for the relief of the dyspnœa and to facilitate measures for the dilatation of the stricture. Intubation may, however, be substituted for tracheotomy in some of these cases.

In all cases of *foreign bodies in the air passages* in which suffocative symptoms persist, and are urgent or frequently recur, and in which the foreign body cannot be speedily and readily removed through the mouth, immediate incision of the trachea is imperative. In a very large proportion of cases the first violent spasms of dyspnœa provoked by the entrance of the foreign body soon subside and a period of calm follows, which may, indeed, last indefinitely. To be able to operate during such a period of calm is highly desirable, for it can then be done with deliberation and with proper attention to those precautions which will prevent the operation itself from adding any new dangers to those already present. The present absence of urgent symptoms should not induce the surgeon indefinitely to postpone operation, in the hope that spontaneous expulsion may occur, notwithstanding the frequent instances in which such spontaneous expulsion is finally effected, for the foreign body is a constant menace to life as long as it remains in the air passages, and is liable to produce sudden death at any time, even in the act of expulsion. Should the dangers of death by asphyxia be escaped, the later development of localized infective disturbances from the presence of the foreign body is inevitable.

Asphyxia from the abundant *entrance of blood, vomited matters, or fluids of any kind into the air passages* calls for tracheotomy and artificial respiration, together with the use of means to free the air passages from the foreign matter that embarrasses the respiration. Asphyxia from the entrance of blood is always to be guarded against in the course of operations about the cavities of the mouth and nasopharynx, when full anaesthesia is required, and every arrangement for immediate tracheotomy should be at hand in those cases in which a deliberate preliminary tracheotomy is not deemed advisable. A person attacked by vomiting while in a state of unconsciousness is in great danger that portions of the vomited material may enter the air passages. The accident of being drowned in one's own vomit is by no means infrequent. It is to be watched for in all cases in which general anaesthesia is induced, and when it occurs demands immediate incision of the trachea and the quick employment of energetic means to free the air passages from the obstructing material. The incision into the trachea not only supplies a new, more direct, and free opening for the entrance of air and facilitates the emptying of the air passages by the compressions used in carrying on artificial respiration, but it affords an opportunity readily to introduce instruments for cleansing the passages. Little can be accomplished in such cases by suction through tubes of any kind; but, by the forcible blowing of air into the lungs through a catheter or other suitable tube introduced through the tracheal wound, the ejection of fluids and semisolids from the air passages by the return current of air may be quickly and readily accomplished.

II. Inflammatory Conditions.—Stenosis of the larynx of such severity as to demand tracheotomy may arise in the course of any of the inflammatory conditions to which the larynx is subject.

In the course of an attack of *acute catarrhal laryngitis*, the rapid development of symptoms of severe dyspnœa, which are not relieved by an emetic or other antispasmodic treatment, indicates the supervention of œdematous infiltration of the aryteno-epiglottic folds and of the epiglottis. The suffocative symptoms produced by this condition may early become so immediately urgent that no opportunity for the use of ordinary therapeutic means is presented, and prompt surgical interference is the only possible thing that can avert a speedily fatal issue. In other cases a more gradual development of the œdema gives time for the employment of remedies, and many of these cases, though in great apparent danger for some time, ultimately end in spontaneous recovery.

Scarification of the supraglottic œdematous tissue has been successful in relieving some of these cases, and in yet others intubation has likewise sufficed to avert danger. But tracheotomy must remain the resource most frequently available to the practitioner who may neither himself have the special technical dexterity in throat manipulations required satisfactorily to practise the last-mentioned operations nor be able to call to his aid others who may have it.

The results of tracheotomy, when done for the relief of acute inflammatory occlusion of the glottis, are very encouraging, and, when the operation is done with the precautions and after-cares to be described further on, very little, if any, additional hazard is added to the case by its employment.

In acute laryngitis the parts below usually remain comparatively unaffected, and after the relief to the obstructed respiration has been afforded by the tracheal incision, the laryngeal inflammatory swelling so quickly subsides that the tube need be retained but a few days. The operation itself contributes to the shortening of the primary laryngitis by putting the affected parts at rest, and removing the source of irritation existing previously in the to-and-fro respiratory current.

The question of chief importance to the physician who is charged with the responsibility of the care of an acute laryngitis is, What degree of urgency must the suffocative symptoms attain to justify him in opening the trachea? He certainly should not wait until the patient is *in extremis*, nor should he be precipitate in action, for spontaneous recovery from very threatening conditions is not rare. At the same time, he is not to consider so much the idea as to whether the patient may not possibly recover without operation as he is to decide whether his chances of recovery will be made greater by the operation.

Tracheotomy is to be accepted as one of the therapeutic resources at the command of the physician for the relief of dyspnœa from laryngeal obstruction, and when the dyspnœa is sufficiently great and prolonged to produce serious suffering, or much exhaustion, the operation is justifiable. The personal element of the skill and experience in the operation of the physician himself must also come into the equation, for, if the dangers inherent in the operation are great, it would be improper to subject a patient to them unless the dangers that were to be averted by the operation were already unmistakably greater and more imminent. Tracheotomy, while often a simple procedure, at times develops conditions that tax to the utmost the coolness, adroitness, and command of resources of the most experienced surgeon. One who is thoroughly provided to control these difficulties would be justified in offering the operation as a means of relief in circumstances less urgent than one without these qualifications.

Loss of voice, frequent thin, metallic, muffled cough, difficult inspiration and prolonged expiration, the suprasternal and epigastric tissues sinking in at each inspiratory effort, great restlessness, suffusion of the face with bluish lips—these are symptoms that, if continued, will produce speedy exhaustion; but in many cases of acute catarrhal laryngitis much of this respiratory difficulty is due to glottic spasm, which may be controlled by treatment, or may spontaneously disappear. If the severe symptoms of dyspnœa are intermittent, if they are lessened in severity and in frequency by treatment, if the general prostration is not great, and if the lethargy denoting advancing defective oxidization of the blood is not marked, tracheotomy should be deferred.

When, on the other hand, the dyspnœa is continuous, and is gradually and steadily increasing despite treatment, especially when symptoms of exhaustion are developing—as shown by pallor of the face, with cold perspiration—and when the benumbing effects of defective aëration of the blood are manifesting themselves—as shown by a tendency to lethargy replacing previous restlessness—then tracheotomy should be resorted to without further delay.

Pseudomembranous Laryngitis.—Of all the causes which may possibly determine dyspnœa of sufficient gravity to require tracheotomy for its relief, the accumulation of a membraniform exudate upon the surface of the laryngeal mucous lining is the most frequent. When the accumulation of such a laryngeal exudate is secondary to, or synchronous with, the same formation within the pharynx or upon the tonsils, early recognition of the cause of the laryngeal symptoms is made; when the earliest manifestation of the exudate is within the larynx, a not infrequent occurrence, the condition cannot be distinguished with certainty from that attending acute catarrhal laryngitis in its severer forms; it is only when, in the progress of the case, membraniform fragments become detached and are expectorated, or a membraniform exudate forms in the pharynx or fauces also, or the presence of the exudate is demonstrated by incising the trachea, that an absolute diagnosis can be made. It is a common error to assume that severe and continuous dyspnœa arising in the course of acute inflammatory affections of the larynx is due to a membraniform exudate, and to denominate the case "membranous croup." This assumption has given rise to many erroneous conclusions as to the value of medicinal treatment in cases of so called membranous croup, for the catarrhal inflammation is much more amenable to medicinal agents than is the exudative. As long, however, as any doubt about the exact character of the case exists, it is wiser, from the standpoint of treatment, to assume that the more intractable disease is present and to guide the treatment accordingly. Such a principle of action will lead to an earlier resort to tracheotomy than would otherwise be the case. If the practitioner has positive evidence, or provisionally accepts the conclusion, that the larynx is becoming blocked by membraniform exudate, his course of action will also be likely to be influenced by his opinion as to the diphtheritic or non-diphtheritic character of the exudative process.

As to the possibility of the development, upon the surface of the laryngeal mucous membrane, of a membraniform exudate not due to diphtheritic infection, there is considerable evidence, consisting chiefly in the undoubted occurrence in localities of cases of membranous laryngitis at rare intervals during a long period of years before the prevalence of diphtheria in that locality.

If such non-diphtheritic cases formerly occurred they may doubtless still occur; but abundant observation has demonstrated that, clinically, it is impossible to distinguish such cases at the present time, and that the symptoms tabulated by systematic writers for establishing the differential diagnosis between the two classes of cases are entirely unreliable, and their importance quite imaginary. The occurrence of membranous laryngitis in any community at the present time is always associated with the prevalence of other forms of diphtheria.

Practically all considerations as to the treatment of pseudomembranous laryngitis resolve themselves into that pertaining to laryngeal diphtheria, and as such I shall consider them in what I may have to say further. The proportion of recoveries from laryngeal diphtheria, without tracheotomy, was exceedingly small, less than ten per cent., before the introduction of the use of diphtheritic antitoxin in the treatment of diphtheria. Present experience indicates that fifty per cent. of such patients may now be expected to recover under the antitoxin treatment without operative interference. The addition of intubation has still further reduced the mortality, so that now about two-thirds of intubated, antitoxin-treated cases end in recovery. The proportion of recoveries in tracheotomized-antitoxin-treated cases is about the same. Of 5,004 intubation-antitoxin cases gathered by Siegert from the records of hospitals for children on the continent of Europe for the period 1890–98 the mortality was 32.4 per cent.; of 6,942 tracheotomized-antitoxin cases the mortality was 32.5. Since, however, tracheotomy is usually resorted to in a more severe class of cases, and at a later date than is intubation, the therapeutic value of tracheotomy would seem to be distinctly greater than that of intubation, which should be preferred only in cases of slight intensity, in cases in which the special cares required after tracheotomy cannot be secured, as well as in those in which the consent of parents to tracheotomy cannot be gained.

The progress of a case from the first inception of symptoms of hoarseness and slight embarrassment of breathing to the termination in death is usually rapid. Out of 1,760 cases of fatal croup in the city of Brooklyn, in children less than five years of age, 57 per cent. died within three days from the onset of the croupy symptoms, 159 died within twenty-four hours, and 22 died within twelve hours. Much time for deliberation is therefore not to be relied upon.

In addition to the exhaustion produced by the unintermitting violent efforts to respire, the deficient blood oxygenation, and the continued depressing effect of the diphtheritic poison, the surgeon must also take into consideration the damage likely to be inflicted upon the lungs themselves during prolonged unrelieved dyspnœa. Pulmonary emphysema and œdema, and diffused capillary hyperæmia, with subsequent bronchial catarrh, result from prolonged dyspnœa, and from complications hindering recovery, should the dyspnœa finally be relieved by tracheotomy. Tracheotomy tends to prevent death in diphtheritic laryngitis by making possible free access of air to the lungs, and thus: (1) Relieving or preventing carbonic-acid poisoning and its sequelæ; (2) supplying the blood freely with the best of stimulants and tonics—oxygen—by which act it assists in the struggle to eliminate the special blood poison, and favors the limitation of the disease; (3) at once ending the cupping-glass action exerted upon the whole surface of the respiratory tract below the larynx by the inspiratory struggles, a result which lessens the danger of the occurrence of diffuse catarrh of the air passages, of pneumonia, and of pulmonary œdema, and promotes recovery from these conditions when not already too extensively developed; (4) rendering respiration free and easy, in consequence of which exhaustion from excessive muscular exertion is either prevented or—if already present—is in some measure relieved.

It tends to prevent death by eliminating from the possible causes of death œdema glottidis, and occlusion of the glottis by a piece of loosened membrane, through the establishment of an opening for the entrance of air at a point between the glottis and the lungs. It prolongs life, and thus gives increased opportunity for the action of remedies, and for a rallying of the powers of nature sufficient to throw off the disease.

By tracheotomy the surgeon is given ready access to the interior of the trachea, and is enabled to remove at once from it any masses of detached exudate that may be present, as well as the abundant pultaceous secretion formed by the mixture of membranous débris and muco-pus which often accumulates below the membrane proper, and is liable to be sucked back into the finer bronchial ramifications, blocking them up and carrying infection to the deepest parts of the lung tissue.

Through the tracheal opening local medication of the trachea and larger bronchia is facilitated, a more direct and accessible way being provided for the introduction of sprays and solutions, forceps and swabs, as the after-course of the disease may require.

The choice of the point at which the trachea is to be opened should also be controlled by the facility with which intratracheal examination and treatment may be carried on through the incision. Without question an incision at some point below the thyroid isthmus gives the surgeon the most advantage in this respect, and for this reason should be chosen, notwithstanding that it demands more care and anatomical knowledge for its safe performance than an incision above the isthmus.

When the one indication for tracheotomy is present, viz., laryngeal stenosis to such a degree as to be a source of danger either directly or indirectly, there can be no contraindication to the operation. Whatever the degree of septicæmia, if the stenosis is great enough materially to intensify it, the operation should still be done.

Coexisting pneumonia, bronchitis, exhaustion, even apparent death, instead of contraindicating, do the more distinctly indicate it. These and other complications render the prognosis more grave, but do not justify a refusal to operate. The literature of the subject abounds in instances in which, despite the gravest complications, recovery has been secured.

Laryngeal tuberculosis, syphilitic disease of the larynx, phlegmonous inflammation of the pharynx or of other structures in the vicinity of the larynx, and chronic hyperplastic laryngitis may each produce such a stenosis of the air passage as to necessitate opening of the trachea for its relief. More rarely spasm or paralysis of the muscles of the larynx may determine a dyspnœa so serious and prolonged as to become an indication for tracheotomy.

Neoplasms may become the cause of an indication for tracheotomy either by pressure from without, as in goitre, or by blocking up the air duct from within, as in carcinoma and papilloma.

Tracheotomy as Preliminary or Adjunct to Other Surgical Procedures.—The preliminary opening of the trachea, and the use of appropriate means to tampon the pharynx or the trachea, and thus to prevent the entrance of blood into the air passages in the course of surgical operations involving the cavities of the nose, mouth, and pharynx, commends itself as a device of great value, and worthy of being assigned an important place in the technique of bloody and prolonged operations in the regions stated.

For a full description of the anatomy of the anterior median region of the neck the reader is referred to the article on *Neck* in Vol. VI., and to that on *Tracheotomy* in the first edition of this HANDBOOK.

ANATOMICAL CONSIDERATIONS.—In the performance of the operation of tracheotomy it is highly important that the surgeon keep in mind the anatomical details of the region in which he operates, both as a guide to the successive steps of the operation and as a monitor to cause him to be prepared beforehand for the exigencies likely to arise during its course.

The vascular conditions in the pretracheal space vary so much that the greatest caution should be used in attempting to approach the trachea through it. There is no line of safety to be preserved. Whatever freedom from other complications may be present, the presence at least of an important venous plexus, covering the trachea in the middle line, will demand special precautions for its avoidance, except in occasional instances.

The loose character of the connective tissue which fills the pretracheal space permits great mobility to the trachea both vertically and from side to side. To this mobility is due the mischance, which has happened to some operators, to miss the trachea altogether, by reason of its having been pulled to one side from the line of incision, and to continue their dissection until arrested by the vertebral column. This lax connective-tissue envelope also permits the burrowing of the tube in front or at the side of the trachea when unskilful or hasty attempts at its introduction are made while the lips of the tracheal incision are not properly retracted, and the field of operation is covered with blood. This tissue also favors the burrowing of pus downward into the anterior mediastinum in certain cases.

The cricoid cartilage, being the most easily and certainly identifiable point along the laryngo-tracheal tube from the outside in children, becomes the most important landmark in the anterior median region of the neck by which to determine the first incisions for tracheotomy. If laryngo-tracheotomy, or tracheotomy through the upper rings by depressing the isthmus, is chosen, the cricoid prominence should fall midway in the incisions; if the low operation is to be done, the incision, beginning above over the cricoid, should extend downward from it to the sternum.

THE DIFFERENT LARYNGO-TRACHEAL INCISIONS.—According to the indications which a special case may present, the air tube should be opened at a higher or a lower point of its course. Operations which involve incision through some part or all of the larynx come under the general class of laryngotomy; those involving the trachea alone, under that of tracheotomy; those involving both, under that of laryngo-tracheotomy.

LARYNGOTOMY.—Incision of the larynx may be partial or total. If it involve only the thyroid cartilage, it is designated as thyrotomy; if the cricoid cartilage, cricotomy; if the cricothyroid membrane, intercrico-thyrotomy.

Laryngotomy is indicated whenever it is necessary to gain access to the cavity of the larynx for the relief of conditions that resist operative attacks through the mouth. These conditions include impacted foreign bodies, certain wounds of the larynx, strictures, some cases of acute perichondritis for removal of necrosed cartilages, and, lastly, tumors of the larynx. Intercricothyrotomy and cricotomy may be resorted to for the relief of urgent and sudden suffocative symptoms that demand haste. The extent and the superficial position of the crico-thyroid membrane in adults, and the ease with which its position may be recognized just above the rigid and prominent cricoid ring, render its opening by a quick plunge of a knife, in cases of emergency, easy and comparatively safe, even in inexperienced hands.

In general, it may be said that section of the thyroid cartilage is to be avoided if the necessary end can be gained by a section restricted to the lower structures of the larynx, because of the subsequent impairment of the voice which must follow the cicatricial agglutination of the anterior part of the vocal bands, which is inevitable to some extent after thyrotomy. The conditions of each case must, of course, determine the decision of the operator at the time as to the extent of the division of the laryngeal structures which he must make. Division of the crico-thyroid ligament and of the cricoid cartilage will be found sufficient for the removal of many laryngeal polypi and subglottic growths; dislocated fragments, in cases of fractures of the cartilages of the larynx, may be reached and manipulated into position through such an incision; necrosed cartilaginous fragments and impacted foreign bodies may likewise be removed thereby. If more room is desired than the partial laryngotomy affords, the prolongation downward of the incision through as many of the upper rings of the trachea as is necessary may suffice, and is to be preferred to total splitting of the thyroid. When, as the result of the condition for which the operation is to be performed, the vocal apparatus has already been irretrievably damaged, the surgeon may split the thyroid cartilage throughout its whole extent without hesitation, if it may seem desirable in order to render his work more facile and radical.

TRACHEOTOMY.—Incisions of the trachea are classified according to their relation to the isthmus of the thyroid gland. If above the isthmus, the incision is tracheotomia superior, or the high operation; if below, it is tracheotomia inferior, or the low operation; if behind the isthmus, it is tracheotomia media, or the middle operation.

Superior Tracheotomy.—The first ring of the trachea being the only one usually exposed above the isthmus, it is evident that sufficient room for a satisfactory opening into the air tube can be gained only by drawing the isthmus down so as to expose the rings behind it, or by extending the cut upward through the cricoid cartilage. In young children the softness and elasticity of the cricoid make easy its incision and the separation of the parts so as to admit of the introduction of a cannula. The high operation, therefore, is to be considered a crico-tracheotomy. Such an operation has a very considerable field for its employment. In general, whenever the air tube must be opened in haste, or by an inexperienced operator, the high operation is to be chosen. The operative difficulties are less, the parts are more superficial, there is less likelihood of the field being occupied by blood-vessels which would embarrass the operation by being wounded. In young children the cricoid cartilage is the most prominent and easily identified structure of the air tube, and presents a landmark which can be recognized quickly, and as quickly and certainly exposed by the knife of the surgeon. When the imminence of suffocation is such as to demand haste in opening the trachea, every other consideration must for the time be held in abeyance; the dangers of hemorrhage and the relative advantage in the after-history of the case of this or that point of incision into the trachea have to be disregarded. Crico-tracheotomy is the operation to be done under such circumstances, on account of the reasons just given.

Median Tracheotomy.—An incision into that part of the trachea usually covered by the isthmus of the thyroid gland constitutes median tracheotomy. The trachea may be exposed at this point either by pulling it down from above, after loosening its attachments, or by cutting directly through the overlying isthmus. In occasional instances the isthmus is wanting altogether, in which cases the median incision becomes a very simple matter. In cases in which, from the shortness of the neck, the existence of large blood-vessels overlying the trachea immediately below the isthmus, the unusual development of the isthmus, or from the persistence of the thymus gland, the exposure of the trachea below the isthmus is difficult or extra hazardous, the median incision is to be chosen.

Inferior Tracheotomy.—In most of the conditions for which tracheotomy is required the low incision is preferable. In stenosis from diphtheritic laryngitis, in cases of foreign bodies in the air passages (unless there is good evidence that the body is fixed in the larynx or high up in the trachea), in many cases of chronic laryngeal disease, in cases of stenosis of the trachea, and in cases of preliminary opening of the trachea to facilitate operations upon the larynx, it is desirable to make the opening into the trachea at some distance below the larynx. The recession of the trachea from the surface, and the plexus of blood-vessels in the deep pretracheal space overlying the trachea, make the operation more delicate, and one requiring more deliberation and experience for its proper and safe performance than the higher operations, but with care and attention to the special operative details which the particular conditions of the region demand, the trachea below the isthmus may generally be easily, expeditiously, and safely exposed.

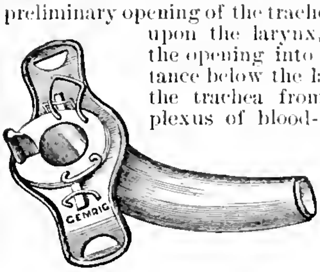

FIG. 4741.—Tracheal Cannula. Ordinary model.

OPERATIVE TECHNIQUE ; INSTRUMENTS.—The list of instruments which experience has shown me to be desirable to have at hand to facilitate the various steps of a tracheotomy comprises a small scalpel; a small, probe-pointed, curved bistoury; a director; a half-dozen pairs of hæmostatic forceps; two pairs of anatomical forceps; suitable retractors for depressing the suprasternal tissues and for elevating the isthmus; an aneurism needle for possible use in ligating the isthmus; a small, sharp, double hook for fixing and steadying the trachea when it is about to be incised; a pair of blunt double-hook retractors for dilating the tracheal wound; a pair of curved forceps for introduction into the trachea, and, finally, a tracheal cannula. Equipped with these instruments, the surgeon will find himself prepared to cope with any emergency likely to arise in the course of the operation, and by their proper use he can make himself to a great degree independent of assistants.

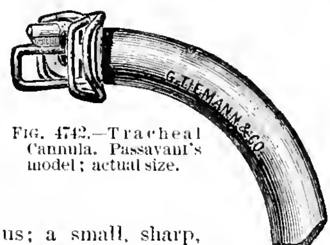

FIG. 4742.—Tracheal Cannula. Passavant's model; actual size.

The Cannula.—In most instances in which tracheotomy has been done, some kind of a cannula will be found indispensable in the after-treatment of the case, to prevent the premature closure of the new respiratory orifice. The model which in general gives best satisfaction is a curved double tube, approximating the quadrant of a circle, which is loosely attached at its outer end to an expanded shield-like plate, to which tapes may be fastened to secure it in place. When this plate is fixed, the tube in the trachea is allowed to move to a considerable extent, to accommodate itself to the movements of the parts. Fig. 4741 shows the cannula as usually found in the instrument shops.

The Material for the Tube.—Silver or aluminum is preferable as the material to use in making the tubes. Hard rubber is objectionable because of the necessarily greater thickness of the walls, which is secured at the expense of the lumen of the tube. Time and use also render the rubber brittle, so that the danger of the tube breaking away from the shield and slipping down into the trachea is created.

For general use four sizes of tubes are desirable, differing in their calibre and curve; and of each size, two different lengths. Let these sizes be denoted respectively by the letters A, B, C, and D, and their dimensions may be presented in tabular form as follows:

MEASUREMENTS FOR TRACHEAL CANNULÆ.

Number of size.	Outside diameter of the outer tube.	Length of the Tube Measured upon its Concave Side from Posterior Surface of Shield to Lower End. Short.	Long.	Radius of the concave side of the tube.
A	5.0 mm.	30 mm.	36 mm.	19 mm.
B	6.5 "	30 "	36 "	21 "
C	8.0 "	40 "	50 "	24 "
D	10.0 "	40 "	50 "	29 "

The shield of the tube should be as narrow as possible, that it may neither embarrass flexion and extension of the head, nor cover too much the wound. The form shown in Fig. 4741 is not so desirable as the one shown in Fig. 4742, in which the lock for securing the inner tube is set at the side instead of at the top, as in the ordinary model.

The lower end of the tube should have both its anterior and posterior walls slightly cut away, as shown in Figs. 4742 and 4743; and this lower end of the inner tube should project slightly beyond the outer tube when pushed fully down into its place. A suitable obtunder, slightly projecting from the lower aperture of the inner tube, is desirable for use during the after-treatment of a case of tracheotomy. Its use facilitates the reintroduction of a tube, and diminishes to a minimum the dangers of excoriations and lacerations which are often produced by attempts to introduce without such aid a tube through a partially collapsed channel.

The fenestra, which is commonly put at about the centre of the convexity of the outer tube, is usually undesirable and should not be present in the ordinary tube. Where it is commonly placed it lies partly outside of the lumen of the trachea and permits the soft tissues lining the cannula sinus to press into it whenever the inner tube is removed, so that often, when the inner tube is replaced, it shaves off a slice of the protruding granulations. Its supposed value in facilitating the early appreciation of ability to breathe through the glottis is fanciful.

ANÆSTHETICS.—Except in cases in which more or less complete insensibility is already developed from asphyxia an anæsthetic should be given. But little will usually be required, and it need not be pushed to the full degree considered desirable for most surgical operations. Chloroform is to be preferred, as less irritating to the air passages, and especially because its dosage and its effects can be more readily and exactly regulated.

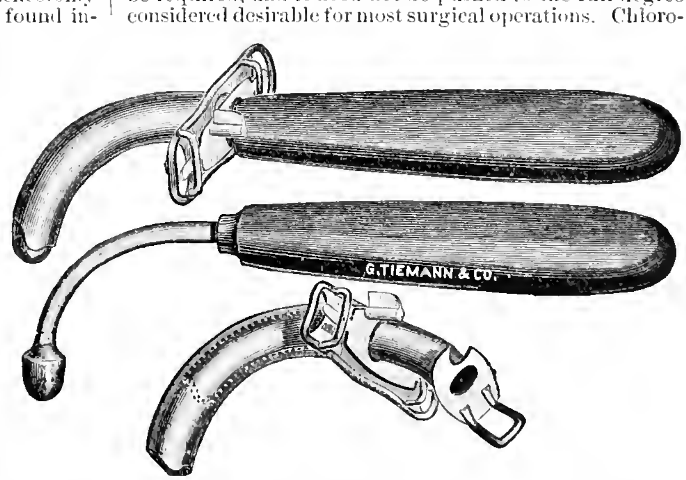

FIG. 4743.—Showing the Relation of the Inner Tube and of the Obtunder to the Tracheal Cannula.

PREPARATIONS FOR THE OPERATION.—*The Table.*—A suitable surface on which to place the patient is the first requisite. It should be high enough to make the surgeon's work convenient, and hard enough to keep the patient's shoulders from sinking down into it. Under no circumstances should the operation be undertaken with the patient lying in bed or in a crib. An ordinary dining or kitchen table answers well. The top of a bureau, if it is not too high, I have repeatedly made use of.

Light.—The more light the better; but usually the surgeon has no choice, and he must make use of what he can get. If the operation is by daylight, the table should be brought close to a window, so that it shall be between the latter and the operator. If the operation is in the night, the lamps and candles must be arranged and held so as especially to illuminate the field of operation. A single candle properly held will give light enough, and is preferable to several lamps placed at a distance. More than one light should, if possible, be provided, lest some mischance to the sole light should cause sudden embarrassment in the course of the operation.

Assistants.—Two assistants are desirable, but if the patient is already insensible, none is absolutely necessary. If an anæsthetic is to be given, one assistant is needed to administer it. He will stand at the head of the patient, and will also be able to render all the assistance needed to hold a retractor or ligate a vessel as the operation proceeds. He may possibly also assist with a sponge, but, as a rule, the operator himself can better do his own sponging. The second assistant is needed only at the feet of the patient to hold the legs quiet and prevent undesirable struggling in case the patient should recover sensibility and should resist before the operation is completed. Any nurse, parent, or friend is quite competent to act as this second assistant.

Sponges.—Small squares of old, soft, and absorbent cotton or linen material, which is always at hand in every household, suffice for sponges. A number of these pieces should be torn and wrung out in hot water, and made ready for use before the beginning of the operation. As fast as one becomes saturated with blood, it is to be thrown away and a fresh one taken.

Miscellanea.—Hot water should be at hand for use in arresting persistent oozing of blood which sometimes is met with; thread for ligating vessels, iodoform for application to the wound surfaces, tape for securing the cannula in position, and a soft catheter or piece of rubber tubing for purposes of insulation, if it should be necessary. A small piece of oiled silk and an ordinary sewing needle, armed with thread, will be needed to complete the final dressing.

THE POSITION OF THE PATIENT.—Everything being ready, the patient is to be placed in position for the

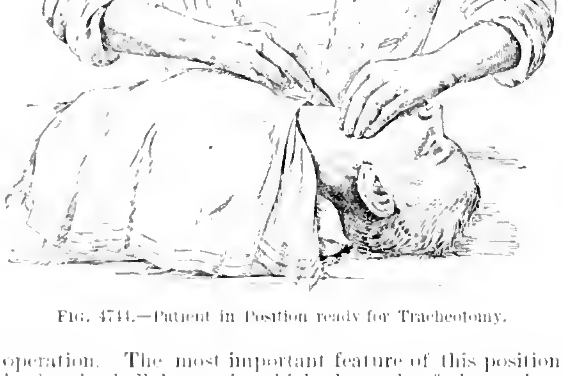

FIG. 4744.—Patient in Position ready for Tracheotomy.

operation. The most important feature of this position is that it shall be one in which the neck of the patient is strongly extended. Upon this point the facility with which the after steps of the operation may be done will greatly depend. A firm cushion should be placed under the shoulders—not under the neck—so as to lift them up and cause the head to fall back and thus extend the neck as the patient lies on the back (see Fig. 4744).

The desired cushion will usually have to be extemporized from articles to be found in the sick-room. A small pillow made into a firm roll; a bundle of clothing; a bottle with a towel wrapped around it; some books; other like materials may serve for the purposes of this cushion. The front of the chest as well as the neck should be made bare, and the field of operation and the adjacent skin should be cleansed with soap and water, if time permits.

THE OPERATION.—*Inferior Tracheotomy.*—The patient being in position and anæsthetized, and the instruments and sponges arranged on a table or chair within easy reach of the operator, he places himself on the right of the patient. The position of the cricoid cartilage is first identified, by the left index-finger, as the first landmark for the operation. The skin is then made somewhat taut, and the larynx steadied by the thumb placed on one side of it and the fingers on the other, as shown in the illustration (Fig. 4744), and at once with a scalpel in the other hand a free incision is made through the skin and superficial layer of the superficial fascia from the cricoid to the upper border of the sternum. Nothing will be gained but embarrassment in the further steps of the operation by making a less free external incision. If any superficial veins have been divided by this first incision, as is often the case, they are secured by hæmostatic forceps. The deeper layer of fascia is now exposed, and not infrequently upon its surface appear large and swollen branches of the anterior jugular plexus of veins, which so closely approximate each other in the middle line as to make it difficult to avoid them in pursuing the dissection further. The operator will be helped to avoid them by seizing the fascia at the lower end of the incision, just above the sternum, with a pair of forceps and nicking through it, and then, having passed a director underneath the fascia upward to the upper angle of the incision, lifting the fascia upon it. By this manœuvre he puts upon the stretch the tissue in the mid-line between the vein trunks, and can slit it up with much less danger of wounding the vessels than if he continued his incision free-hand. If, however, no vessels appear demanding this use of the director, the deeper layer of fascia may be divided without delay by a stroke of the scalpel to an extent corresponding with the cutaneous incision. A pair of hæmostatic forceps is now fixed in the free border of the incised fascia on either side and permitted to fall outward upon the side of the neck; this retracts the wound edges and freely exposes the connective tissue which joins the inner margins of the anterior ribbon muscles of the neck. The operator now seizes this connective tissue between two pairs of anatomical forceps, and, by causing them to pull against each other again and again, tears his way down to the trachea and freely opens up the pretracheal space. As the dissection deepens, the forceps which have been used as retractors are fixed in the deeper layers of tissue which have been opened up, until they are finally fixed in the tissue that ensheathes the trachea on either side, at the same time securing any bleeding veins that may be torn, while they continue to act as efficient retractors. The inferior thyroid plexus of veins will be identified, as its branches are exposed, and may usually be easily drawn aside and secured out of the field of the dissection by the retracting forceps. At the upper angle of the wound the lower border of the isthmus may encroach upon the field, especially if the isthmus is unusually broad. The clearing away of the pretracheal space should always be thorough enough to uncover and clearly define the lower border of the isthmus. If the breadth or low position of the isthmus is such as to hinder the ready and sufficient exposure of the trachea, it should be pulled up by a proper hooked retractor and held out of the way by an assistant If, now, all these precautions have been taken, the trachea will be found to be quite superficial and accessible, on account of the way in which the retracting forceps on either side lift it up from its bed and press back the wound borders. The anterior surface of the trachea should now be cleanly exposed by tearing through any connective tissue that may still cover it; any large vessels that may have been unavoidably wounded and temporarily secured by forceps should be tied; if possible all capillary oozing should also be stanched, although if the method described is adopted it will be rare that any troublesome hemorrhage will be met with. The anterior wall of the trachea is now to be hooked up in the middle line by a tenaculum, and held steadily by the operator with one hand, while, with the scalpel in the other hand, he pushes the point of the knife through the wall of the trachea into its cavity. The hiss of escaping air announces that the cavity of the trachea has been penetrated. The sharp-pointed scalpel is now laid aside, and the probe-pointed, curved bistoury is taken and, its point having been introduced through the opening into the trachea, the incision is carefully enlarged, either upward or downward, as may seem most judicious in the particular case, until the length of the incision is at least one and a half times as great as the diameter of the tube which is to be inserted. The incision should be made deliberately, with a full and exact knowledge of just where and to what extent tissue is being cut. Except in the most urgent cases, in which respiration has already actually ceased, there will be ample time to make the careful and systematic approach to the trachea which has been described. The doing of it takes by no means as much time as the description of it; for one who is at all experienced in the work, five minutes will not be required from the time the first incision is made till the cut in the trachea is accomplished and the new respiratory orifice is provided. As soon as the cut into the trachea has been made, the operator takes the tracheal retracting hooks, and, placing the hooks in the incision, from either side retracts the edges and dilates widely the new opening. One or both of these hooks may now be entrusted to an assistant, while the hands of the operator are set at liberty for the further cares which the case may demand. A tube should not at once be thrust into the opening, but it should be kept patent by the retractors, while a careful inspection of the interior of the trachea is made. In many cases in which the operation has been done on account of pseudomembranous disease, immediately upon the incision being dilated, there will occur a copious ejection through it of membranous débris and of muco-pus, and not infrequently of large membranous flakes, and even complete casts of the trachea. If the respiration has apparently ceased and artificial respiration is resorted to for resuscitation, firm compression of the thorax may cause the liquid contents of the trachea and the bronchi to well up out of the opening. Every care by immediate sponging should, of course, be taken to prevent the sucking back into the trachea of these materials.

In the cases in which tracheotomy has been done on account of a foreign body in the air passages, the exploration of the trachea for its detection and removal will follow as the next step after the trachea has been opened into. When the healthy trachea has been opened for the relief of laryngeal obstruction, or for preventive reasons, the immediate insertion of a cannula is to be made; in the cases, however, in which the trachea, when opened, is found to contain an exudate that is in process of exfoliation, every effort should be made to secure its removal before the cannula is introduced. For this purpose a chicken's feather may be passed down into the trachea and twisted about. This will often be efficient in detaching membranous bits and in provoking a spasm of coughing sufficient to expel them. Curved exploring forceps may be carried down into the trachea directly to seize and withdraw portions of exfoliating membrane. Their introduction will cause a strong expulsive cough, which will tend to loosen and drive between their open jaws any exudate not too firmly attached. I often fasten a small piece of sponge or soft rag in the jaws of the forceps, and introduce the forceps thus armed into the trachea, like a swab, more thoroughly to cleanse its interior. If, by any mischance, considerable blood should have entered the trachea from the operation wound, the same measures to secure its removal, as far as possible, should also be resorted to.

Before the cannula is put in place, while the tracheal opening is still kept patent by the hooks, the toilet of the external wound should be made. All hæmostatic forceps still in use should be removed, and final hæmostasis effected. The wound surfaces should be lightly dusted with iodoform or bismuth, after which the cannula, armed with its retaining tape, should be gently put in place, its tracheal portion being slipped into the trachea, while the edges of the tracheal wound are sufficiently separated by the dilating hooks to permit its entrance. If the cannula is so large as somewhat to distend the trachea, and it is necessary, or is deemed best, to use so large a one, it should not be crowded down the trachea; but if its end is once fairly engaged within the trachea, it will soon gradually work its own way down as far as it can get. The immediate effect of the introduction of the cannula is to excite a spasm of coughing, which, however, usually soon ceases. The cannula should be gently held in place by the fingers of the operator until this storm of coughing has subsided. The tapes should then be passed around the neck and tied so as to hold the cannula securely in place. Care should be taken, in tying the tapes, not to draw them too tight at first, but, while they are tight enough to prevent the end of the tube from slipping out of the trachea, still to have sufficient slack to provide for the swelling of the neck from infiltration of the borders of the wound, which always occurs within the first twenty-four hours after an operation. Otherwise the tapes will soon become too tight, and will cause much suffering to the patient if delay in frequent examination of them should occur.

The final dressings may now be applied. If the external wound has been made so freely upward as to extend considerably above the upper edge of the shield of the cannula a single suture may be applied so as to diminish the extent of the gaping here; but this will rarely be required. No attempt at suturing the lower portion of the wound should ever be made, lest retention of secretions and their burrowing downward behind the sternum be occasioned. A small compress should be made out of any thin, soft material, as an old pocket-handkerchief, or prepared gauze. It should be large enough to cover the wound and extend out on either side to the outer border of the flanges of the shield of the cannula. This compress should be slit down to its centre on one side so as to facilitate its application around the tube; it should then be smeared with an ointment of oxide of zinc and salicylic acid (oxide of zinc, gr. x.; salicylic acid, gr. iij.; vaseline, ℥ ss.), and, finally, should be applied around the tube and under the shield, so as to cover and protect the whole wound. Next, a bib made of oiled silk should be applied to the front of the neck and half-way down the front of the chest. It should be secured around the neck, having been cut away at the top so that its upper edge may easily be slipped under the lower edge of the shield, between it and the compress. The object of this is to protect the necessarily exposed parts of the chest from the air and from the secretions continually being expelled through the tube. Finally, a small veil made of two thicknesses of gauze or similar material, or a thin, flat sponge wrung out in hot water, should be adjusted over the external opening of the cannula to keep out dust and to moisten somewhat the inhaled air; the dressing is now complete, and the patient may be removed to his bed.

Superior Tracheotomy.—If the trachea is to be entered above the thyroid isthmus, the cricoid cartilage is again the landmark which is first to be identified. The skin and superficial fascia are to be divided by an incision at least one and a half inches long, the centre of which should fall upon the cricoid. The deep fascia may next be divided by free dissection, or upon a director. The thin connective-tissue layer which lies underneath is then to be divided carefully, or torn with forceps, so as to expose the surface of the cricoid. A careful transverse incision or tear of the fascia, which is attached to the lower border of the cricoid, is then to be made. This will loosen the isthmus from its attachment to the trachea, and now, with a suitable hooked retractor, the isthmus is to be pulled downward as far as possible. The upper two or three rings of the trachea are now exposed; the sides of the wound should be kept apart by the catch-forceps, as in the low operation, the fixation hook should be inserted into the cricoid, and a longitudinal incision, cutting from below upward, made through the exposed rings of the trachea after the manner already described. If the incision made into the trachea does not give room enough for the easy introduction of the cannula, the cricoid also is to be divided. The toilet of the trachea and of the wound, and the placing of the cannula, are to be done in the same way as already described for the low operation. In those urgent cases in which at every hazard an immediate opening must be made into the windpipe, the following method is to be followed: It is the work of but a moment to get the child upon a table, get a book or cushion under its shoulders, and tear away the clothing from in front of its neck. The larynx then being steadied and made prominent by the thumb and fingers of the left hand, with one free stroke of the scalpel in the other hand, all the superficial tissues are divided down to the cricoid and the isthmus; possibly the latter is also divided by this single cut. Does free bleeding follow the cut, the tissue from which the bleeding comes is seized *en masse* in the grasp of an hæmostatic forceps, with another stroke of the scalpel the trachea is opened, then the hook retractors are inserted, and the opening is dilated. There is always some one by to whom the dilating hooks can now be entrusted, while the surgeon institutes artificial respiration if needed, or seizes any vessels that may be bleeding, or removes any masses of exudate that may be blocking up the trachea. Free respiration having been re-established, haste is over, and all that is further required, including the introduction of the cannula, may be done with deliberation.

Complications of the Operation.—Varying conditions of pretracheal vascularity may embarrass the ready performance of any of the different methods of tracheotomy. It is by ignoring these conditions, by using too much haste in operating, by the lack of needed instruments, or by other imperfections in operative technique, perhaps unavoidable on account of emergency, that most of the serious accidental complications of tracheotomy are caused. The following list of complications is to be considered: Hemorrhage, asphyxia, displacement of the trachea, faulty incisions into the trachea, failure to introduce the cannula into the trachea, emphysema, and fatal syncope.

Hemorrhage.—The occurrence of hemorrhage is the most frequent of the accidents that complicate tracheotomy, and the one which brings in its train most of the other accidents enumerated. None of the precautions for the avoidance of hemorrhage which have been described in the section devoted to operative technique is unimportant. It is important that, if possible, bleeding should be arrested before the trachea is opened, but it may happen that delay for such a purpose may itself be fatal from the unrelieved asphyxia. When suffocation is imminent, therefore, the surgeon must, regardless of hemorrhage, boldly and rapidly proceed with his efforts to open the trachea. When the trachea has thus been opened through a pool of blood, the immediate introduction of the cannula is required, for the special purpose of preventing the flooding of the trachea with blood as well as for furnishing a conduit for the air. As soon as free respiration is again established, the bleeding will usually cease spontaneously, or may easily be controlled by pressure.

Hemorrhage from the vessels of the tracheal mucous membrane may also be a source of trouble. However perfectly bleeding may have been arrested before the trachea is opened, some hemorrhage from the divided vessels of the tracheal mucous membrane will follow the incision of the trachea. The blood flows into the trachea, but its flow usually ceases spontaneously, and the small quantity that has been effused is readily coughed out.

Cases of persistent internal hemorrhage from the tracheal vessels proper are fortunately rare. In such instances there will have been profound blood-poisoning antecedent to the operation. The method of operating, and of dealing with the trachea, which has already been advocated in the previous pages of this paper, will be the one best adapted for early discovering and successfully overcoming this complication.

Asphyxia.—The asphyxiative symptoms may be aggravated in some cases by the anæsthetic itself. Another source of aggravation, incident especially to the low operation, is liable to be present in very young children whose tracheal rings are not very resistant. When the deep fascia is incised and the deep pretracheal space is opened up, an important protection to the trachea from external pressure is lost, so that the soft tube is exposed to the full effects of atmospheric pressure at every attempt at respiration. A certain amount of collapse of the trachea may thus be caused, with speedy asphyxia unless the tube is quickly opened. This will occur, of course, only when the laryngeal obstruction is already very great, and therefore is more likely to complicate those operations that are deferred until the suffocative symptoms have already become extreme. This is the cause of the marked increase in the asphyxiative symptoms which so often develop during an operation, and alarm the surgeon lest the patient die before the trachea is opened. It is just at this crisis that, in his haste and solicitude, the operator is most likely to wound a vessel and add to the existing perils the dangers and difficulties of a sudden flooding of the wound with blood. To delay to stanch the bleeding would be fatal, to find the trachea through the deep, narrow wound filled with blood is difficult, and to incise it thus obscured is hazardous; but nevertheless, in such an emergency, it must be done as the only resource. The surgeon may properly protest against the delay in operating which should expose his patient to such perils, but in many cases the time of operating is not a matter of choice, for he may not arrive at the bedside of the patient until extreme symptoms have already developed. As soon as the trachea is opened, if done under such circumstances of hemorrhage, the patient should be turned over on his face to prevent the flow of blood into the trachea; if breathing has already ceased artificial respiration must be instituted; if the trachea has been flooded with blood it must be forced out by compression of the thorax, and by blowing air into the bronchi through a tube, as a catheter, so as to excite expulsive cough. It should be noted, however, that in any case the amount of time required for such a careful and systematic exposure of the trachea as would suffice to guard against operative mischance is so short that the surgeon need rarely feel himself compelled to depart from the cool, safe, and regular prosecution of his work. The preservation of a dry wound, and the obtaining of a clear, unobstructed opening into the trachea are the very best safeguards against the occurrence of uncontrollable asphyxia, and to secure these he may well disregard for the moment threatening asphyxia, relying on his ability to re-excite respiration by artificial means if it should actually cease before the opening in the trachea is made. Fatal asphyxia may be caused by a plug of false membrane crowded down into the trachea before a hastily introduced tube. A thick and loosely adherent lining of membrane may be pushed before the point of the knife which cuts the more resistant tracheal wall, and a hastily introduced tube, pushing its way between the membrane and the wall of the trachea, may find itself within the trachea, but still shut off from its cavity by this membranous layer. Death from asphyxia may occur before the cause is recognized and remedied. In general, as to these dangers, it may be said that prevention is better than cure. If care is taken to have the trachea clear of loose exudate before the cannula is inserted, such accidents cannot happen. If, however, as the result of circumstances beyond his control, the surgeon finds himself confronted by this accident, as indicated by increased embarrassment to the breathing or its total cessation upon the introduction of the cannula, the latter must be at once withdrawn, the tracheal opening dilated, perhaps enlarged, and, by the use of forceps, swabs, syringes, inflating tubes, or feathers, the cavity of the trachea must be quickly cleared, and artificial respiration resorted to.

Displacement of the Trachea.—The trachea may have been dragged or pushed away from its proper position in the median line by tumors. A more frequent cause of displacement of the trachea is unequal retraction of the borders of the wound in the course of the dissection to expose it, or unintentional departure from the midline of the neck by the surgeon. The result is that the operator strikes the trachea laterally, or misses it altogether. Cases are recorded in which the operator, having thus missed the trachea, has continued his dissection until the vertebral column was reached. Such mischances are most likely to occur when the field of operation is obscured by blood, and an inexperienced operator is under the pressure of symptoms demanding haste.

To guard against such accidents it is important that the landmarks for the operation which have been described in earlier sections be identified at the outset of the operation, and that, when haste in operating is imperative, the larynx should be steadied and the tissues evenly retracted by the fingers of one hand, while the incisions are made with the other.

Faulty Incisions into the Trachea.—These include lateral incisions, multiple incisions, too short incisions, too long incisions, and complete transfixion of the trachea with penetration into the œsophagus. They are generally the result of haste and hemorrhage. A lateral incision will make the cannula stand awry upon the surface of the neck, and increase the dangers of irritation to the tracheal mucous membrane from its extremity. Multiple incisions are the result of repeated ineffectual stabs at the trachea when the first incision is lost beneath shifting tissues or in a pool of blood.

When a puncture has been made and lost, so that it cannot quickly be found again, time should not be wasted in searching for it, but a new incision should be made. Too short an incision interferes with the ready introduction of a tube; too long an incision leads to difficulty in retaining a tube in the trachea. The length of the incision should not exceed one and a half times the diameter of the tube that is to be inserted, and when the tracheal cartilages are too rigid to permit ready separation of the edges of the incision to a sufficient extent, exsection of a portion of them should be done.

Complete transfixion of the trachea may easily be done in young children in whom the tracheal walls are quite soft, and possibly already somewhat collapsed. It is to prevent this accident that the recommendation is made to hold up and steady the anterior wall of the trachea by a fixation hook or tenaculum before it is carefully pierced by the point of the knife. Attempts to open the trachea by quick thrusts of the knife should never be made.

Failure to Introduce the Cannula into the Trachea.—Death before the cannula is introduced, on account of delay from some of the accidents already mentioned, has occurred many times. There can be no excuse for leaving a cannula thrust down by the side or in front of the trachea. Such an accident can happen only when the incision in the trachea is imperfectly exposed and retracted, perhaps hidden by blood, or when the trachea has been missed altogether. The rush of air through the tube when it enters the windpipe is unmistakable, and the operator should never be satisfied until the free current of air in and out of the tube clearly demonstrates that it is properly in place.

Emphysema.—When emphysema follows a tracheotomy, it must be produced by some operative mischance whereby the peritracheal connective tissue is opened up deeply without corresponding external wound, or lateral or multiple incisions into the trachea have been made, or an incision into which the cannula either has not been introduced at all or has slipped out of, so that the expired air is forced into the connective tissue. Though the cannula may have been properly introduced at first, it may slip out of its place later, either because too loosely tied in, or because the tracheal incision is too long, or because the tracheal cannula is too short from the first, or the subsequent tumefaction of the tissues lengthens the track so that it becomes too short later.

The appearance of the emphysema may be first noted during the operation, or it may not be noted until some hours have passed, depending upon the time when the causes of it become active. It may be limited to the region of the wound, or may in extreme cases become generalized. As soon as its cause is removed, it will rapidly subside.

Syncope.—A transient syncope occurs in some cases immediately upon the incision into the trachea being made, caused by the sudden free in-rushing of an abundant stream of air. For a moment further inspiratory efforts cease, and the child appears as if it would never breathe again. There is no cause for anxiety, however, since the momentary shock is quickly rallied from and regular respiration begins again. Compression of the thorax and dashing cold water into the face of the patient may be resorted to, if the syncope is prolonged.

Fatal syncope may occur at any stage of the operation in children who are the subjects of diphtheria, from heart failure determined by agitation, hemorrhage, or possibly the anæsthetic.

After-treatment.—Much difficulty is often experienced in inducing children to take the needed amount of food, not necessarily because it hurts them to swallow, but because of their general state. Not infrequently, also, such paralytic weakness of the pharyngeal and laryngeal muscles develops that, at every attempt to swallow, more or less food will enter the larynx and provoke violent coughing. Rectal enemata, or feeding through an œsophageal tube, must be resorted to in such cases. The general principles of dietetics which are recognized in other cases attended with exhaustion will find their application in the after-treatment of tracheotomized patients. The air should be pure and abundant, as well as warm and moist. I can see no advantage to be gained from shutting up the patient in a close tent, or in maintaining the temperature of the sick-room at a very high point and having it filled with steam, which cannot be equally well obtained from simple and less depressing measures. A temperature of from 72° to 75° F. is high enough. The floating dust of the air should be strained out, and additional moisture given to the in-going current of air by keeping the orifice of the tube covered with a moist veil or sponge. The fact must not be lost sight of that the pre-existing condition of congestion of the pulmonary and bronchial capillaries induced by prolonged dyspnœa predisposes to the development of pneumonia and bronchitis—of which the entrance of blood into the air passages, the aspiration of portions of food and of necrotic bits of exudate, or unhealthy secretions from the larynx and trachea, may frequently be the final determining cause. It is important, therefore, to keep from the respiratory tract as far as possible every depressing influence; hence the importance of the injunction that the air supplied should not only be warm and moist, but also abundant and pure. In no class of cases is the value of intelligent and careful nursing more marked, and it would be greatly to the advantage of the little unfortunates in large cities, where diphtheritic croup prevails, if all such cases could be kept after tracheotomy in special wards of hospitals, equipped with every facility for their proper care. Traumatic fever, to some extent, is unavoidable from the character of the wound. If no complication in the course of the wound healing takes place, the fever will demand no special treatment; if it is excessive and prolonged, the cause for it is to be sought in some complication to which appropriate treatment must be directed.

In addition to the general cares above outlined, special care will be required for the management of the wound, of the trachea, and of the cannula.

THE WOUND.—In general, the cares which the wound will demand are very simple; while it remains open, its secretions, together with any tracheal secretions that are ejected upon it, readily flow away. No dressing should ever be applied which would favor the retention of secretions in the wound. Twice daily, the wound should be lightly dusted with iodoform or bismuth to prevent septic changes, while the wound, as a whole, should be kept protected from external irritation by a small square of linen or similar material laid over it, smeared with an emollient, like the salicylated zinc ointment, already mentioned. The removal of dried crusts and the general cleanliness of the adjacent parts must be looked after on general principles. After the cannula has been dispensed with, the wound rapidly contracts, the cannula fistula collapses, its walls quickly adhere, and a simple superficial granulating surface is left, the treatment of which is conducted on general principles. The rapidity with which these reparative changes take place will depend on the amount of the previous disturbance of the wound and on the general vigor of the patient. When much loss of substance has taken place, or the cannula has been worn for a long time so that its sinus has become lined by a well-organized membrane, a permanent fistula may remain, the obliteration of which may require a plastic operation.

Phlegmon of the Wound.—Some phlegmonous inflammation of the borders of the wound is common. They become tumefied and indurated, and a zone of redness extends to a variable extent outward upon the skin of the neck, and downward upon the thorax. Little tendency seems to exist to the formation of abscesses—at least I have never observed it; the necrotic changes which it determines in its more intense forms take place on the surface, and may range from slight ulceration to extensive sloughing. If erysipelas or diphtheria is engrafted upon it, these necrotic changes will be aggravated. This wound inflammation is septic in character, and aggravated by the irritation of the cannula. It begins to manifest itself more especially during the third day; if life is prolonged and the case does well in other respects, it will begin to subside after three or four days, especially if the cannula can be dispensed with. An efficient antiseptic treatment of the wound from the first, as already advised, is the best preventive of this phlegmonous invasion, and the best curative, if the invasion has already taken place. The inflamed integument should be kept anointed with carbolated oil (carbolic acid, three per cent.), or an ointment of ichthyol (ichthyol or ichthyolate of ammonia, ten per cent.). The cannula should be kept out of the wound as much as possible. Even though the condition of the larynx may not permit of the permanent removal of the cannula, still the stiffness of the wound borders will suffice to keep the track of the cannula patent enough for respiration for quite a while after the tube has been taken out, so that the patient may be able to get along without the latter for from fifteen to sixty minutes or more at a time, before it becomes necessary to replace it. After the tube has been in place for an hour, it may be removed again, and so on as long as the persistent wound inflammation may require such help. In such cases as this the use of a suitable obturator to facilitate the reintroduction of the tube (see Fig. 4743) is especially needed. With the help of such an obturator any intelligent nurse can carry out this procedure. Erysipelas of the wound is characterized by a more extreme spreading of the skin inflammation, is simply a more severe form of septic disturbance of the wound, and is to be antagonized by the same kind of treatment.

Diphtheria of the wound demands no special treatment different from that given to the phlegmonous inflammation which attends it. If the case does well in other respects, the exudate exfoliates spontaneously in due time, and cicatrization proceeds.

Gangrene of the Wound.—This may manifest itself either in a progressive ulcerative process that converts the wound into an ill-conditioned spreading ulcer, or in the formation of distinct sloughs of necrosed tissue. Its causes are the same as those of the less severe forms of septic infection already noted, and indicate a more intense form of infection and less local and general resisting power on the part of the patient. A black discoloration of the cannula, caused by the disengagement of sulphureted hydrogen, indicates the beginning of the gangrenous process. The treatment consists in the use of local stimulants and antiseptics, and general tonics, and the suppression of the cannula as much as possible. If the gangrene is superficial, the sloughs are soon cast off, the wound assumes a healthy appearance, and its cicatrization proceeds without any permanent damage having been occasioned. Every degree of disorganization may, however, occur, even to the invasion of the larynx and trachea. An extreme loss of substance, if ultimate cicatrization should be accomplished, would entail stenosis of the windpipe requiring permanent wearing of the cannula.

Secondary Hemorrhage.—Bleeding may take place at any time during the after-history of a case until all ulcerative tendencies have been arrested. It may be due to the reopening of a vessel wounded during the operation, to the erosion of the coats of a vessel through the pressure of the cannula, or to the falling of a slough. Not infrequently the expectoration becomes tinged with blood from time to time. This is due in most instances to slight erosions of the tracheal mucous membrane by the cannula, most frequently at its point, and calls either for greater gentleness in the manipulations about the cannula, or for a change in the tube itself, so that, by having one of a different length or different curve, the ulcerating point may be relieved from pressure. Many cases of profuse and fatal secondary bleeding have been reported. Such hemorrhages are due usually to eroded tracheal vessels, but may be due to the opening by ulceration of some vessel in the external wound. In a number of reported instances the innominate artery has been the source of the bleeding. The possibility of serious secondary hemorrhage should always be borne in mind, and every care should be taken to prevent or limit the ulcerative processes upon which it depends. When a large vessel is the source of the bleeding, the immediate inundation of the air passages with blood will cause speedy death. If the bleeding is less overwhelming in its onset, the bleeding point must be sought for, and the flow stanched by the use of the ordinary means available for hæmostasis.

THE TRACHEA.—*Pseudomembranous Exudate.*—The extent and character of intratracheal exudations is one of the most important conditions upon which the success of tracheotomy depends, especially in cases in which the operation is performed in the course of diphtheria. The amount of the tracheal mucous surface that may become involved in the pseudomembranous exudate varies much, and it is generally impossible to determine, previously to the opening of the trachea, whether the exudate extends below the larynx or not; in a large proportion of cases it remains limited to the larynx throughout; in others, if life is prolonged by tracheotomy, it afterward extends to the trachea and to the bronchi; in many the trachea is involved from the first; of these, in some, after the exfoliation of the exudate already formed, no further deposit occurs; in others its progressive formation leads irresistibly to death. When the trachea already contains an exudate at the time of operation, more or less extensive particles of it, accompanied by much muco-pus, will often be ejected through the incision when made. In other cases, in which the exudate is still adherent, it may be possible to secure the detachment and expulsion of portions of it by the introduction through the wound into the trachea of suitable instruments, as already advised in a previous section.

The readiness with which exfoliation of the membranous exudate takes place, depends upon the degree to which its elements adhere to and penetrate the mucous membrane beneath, which again is a very fair index of the intensity of the local inflammation. The cases marked by a ready exfoliation are those in which the depth and intensity of the local disease are slight, and which give a ready hope for recovery, provided that the special dangers incident to the location of the deposit be overcome.

In many of the cases in which the loosened exudate is ejected upon the first opening into the trachea, or is easily removed at once, unimpeded and speedy recovery will ensue if only the simplest precautions be taken to protect from hurtful extraneous influences.

Much more frequently, however, the detachment of the membrane is delayed, and it takes place in smaller masses, of varying size, that appear from time to time in the expectoration during the after-progress of the case. These loosened pieces of membrane, usually mingled with viscid mucus or muco-pus, are often expelled with difficulty; they provoke suffocative crises that for a time seem to threaten the utmost peril; and in not a few instances, when skilled and instant assistance is not rendered, they produce death by blocking up the lumen of the trachea, or of the cannula that may be in use. In any case in which there has taken place a membranous exudate within the trachea below the point of incision, such a suffocative crisis is likely suddenly to arise at any time during the period of its exfoliation. These are the cases in which the ultimate result depends directly upon the completeness with which the indications presented by the presence of this loosening membrane are appreciated, and the faithfulness and thoroughness with which they are carried out.

Catarrhal Inflammation.—Some catarrhal inflammation of the tracheal mucous membrane always accompanies a membranous exudate, and frequently causes conditions that complicate greatly the after-treatment. It is liable to be excited *de novo*, in cases not associated with membranous exudate, by the inhalation of unmodified air—cold, dry, and dust-laden—through the new respiratory aperture. It may extend to the smaller bronchi; it is the immediate cause of death in a considerable proportion of cases after tracheotomy.

Even in cases in which the catarrhal inflammation does not extend beyond the trachea or the primary bronchi, the secretion may be so copious and so viscid that the air passage can be kept clear with difficulty; where there is membrane also present, it is by the catarrhal secretion that the membrane is lifted up and disintegrated; this secretion mingles with the membranous shreds that are expectorated and may cement them together in masses too large to be expelled without assistance; it clings to the interior of the cannula, where it readily dries in the air current and forms incrustations that rapidly diminish its lumen. The greatest trouble from this catarrhal secretion is usually experienced within the first three or four days after tracheotomy. It then either diminishes greatly in quantity, or becomes muco-purulent and diffluent. In many cases the character of the secretion has already become muco-purulent before the incision into the trachea is made, in which case its copious and ready expulsion through the opening then takes place.

The indications for treatment of catarrhal inflammation of the trachea are to limit its extent, to modify its intensity, and to obviate dangerous accumulation of its secretions.

The first two indications may be fulfilled by the same measures. Whatever remedial measures have been recognized as of value in the treatment of inflammations in general of the respiratory mucous membrane, will be of equal value in these cases, and will be applied according to the experience of the individual practitioner. Calomel, antimony, and muriate of ammonia each possess a positive influence in promoting free secretion and rendering it less viscid, but in the majority of cases dependence will be mostly placed on local applications.

The air inspired must be warm, moist, and pure. The use of the moist sponge or gauze veil over the mouth of the cannula, advised in a previous section, should be kept up. If necessary they may be held in place by tapes fastened at either side, and tied over the head or around the neck. In addition to this precaution, whenever difficulty is being experienced by the patient in fully coughing out the tracheal secretions, inhalations of vapor, instillations and injections of liquids may be practised. Inhalations of steam, of steam charged with vaporized Peruvian balsam, with atomized lime water, or with solution of muriate of ammonia, may be used with benefit. Instillations and injections are also of great advantage. When the symptoms are not urgent, three or four drops of warm water and chloride of sodium, of lime water, or of dilute lactic acid, may be made to run down through the tube into the trachea as often as seems to be necessary to keep the secretions diffluent and the expectoration free. Whenever this is not sufficient to prevent the continued marked accumulation of secretions, whether of tenacious and inspissated mucus or of muco-pus and membranous débris, injections of the solvent liquid, to the amount of a drachm or more, are to be made by means of a syringe introduced deeply into the cavity of the trachea. For this purpose a small syringe, as a hypodermic syringe, having a tube attached to it of suitable size and curve to pass through the cannula, terminating in a perforated bulb, as shown in the illustration (Fig. 4745), is desirable. In making the injections, the bulb is quickly passed down through the cannula, or through the wound after the cannula has been withdrawn, for an inch or more into the trachea, and the liquid is injected with some force. A violent expiratory paroxysm follows, the diluted and loosened mucus is dislodged and expelled; after a minute or two the injection may be repeated, and will be followed by still greater relief. These injections may be repeated from time to time, as often as the reaccumulation of viscid mucus in the air passage is evident.

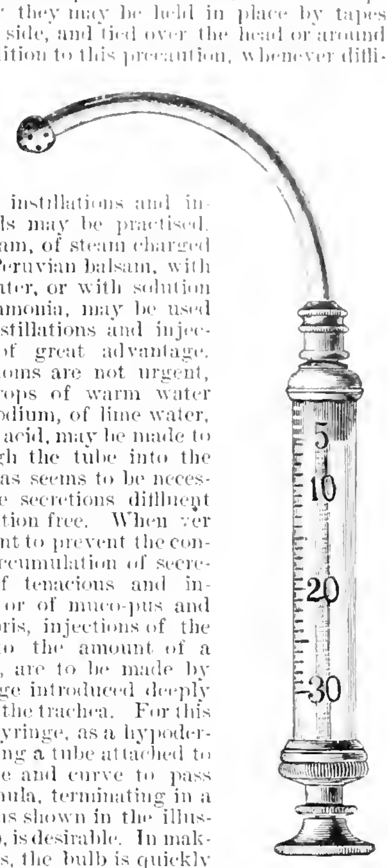

FIG. 4745.—Syringe for Intratracheal Injections.

Pressure Sores.—The possible erosion and ulceration of the tracheal walls from the pressure and friction of the cannula is always to be borne in mind. The mere pressure exerted by the cannula does not seem to be the only thing at fault in the development of ulcerations of the trachea, as the prolonged wearing of a cannula after tracheotomy for conditions other than diphtheritic croup, and even in many of these cases, without unpleasant pressure effects ever being experienced, is sufficient to prove. The vitality of a tissue which has been the seat of a diphtheritic exudation is diminished; it naturally tends to necrosis; the more intense the diphtheritic process, the greater the necrotic tendency. In such cases the slight additional irritation afforded by the pressure of the cannula suffices to determine a slough. That in the movements of the neck, and in the manipulations of the tube, frequent antero-posterior tilting of the cannula should be done is unavoidable; and it would be expected that the striking of the anterior edge of the inner end of the cannula against the anterior wall of the trachea in these frequent tiltings would cause that point to be the one at which ulceration should most frequently take place.

Many cases of mere erosion or of slight ulceration undoubtedly pass unnoticed. The most important symptoms which indicate the existence of ulceration are two —namely, the appearance of bloody streaks in the expectoration some days after the operation and a black discoloration of the lower end of the tube.

It is on account of the danger of these pressure effects that so much stress has been laid in a previous section on the use of such a form of tube as shall in its construction provide as perfectly as possible against friction and pressure while it is worn. For the same reason efforts to dispense with the cannula should be begun very early, and whenever evidences of pressure effects are detected, its removal, if but for a short time at any one trial, should be frequently practised. In cases of the high operation the cannula may possibly sometimes be dispensed with altogether.

Granulation Vegetations. — Exuberant granulations, forming polypoid excrescences projecting into the trachea, have been noted by many observers; they may be sessile or pedunculated, single or multiple; they most frequently occupy the superior or inferior angle of the wound, at which points a small space exists not occupied by the cannula, which is early filled by granulation tissue and is constantly subject to the irritation of the tube thereafter.

Whenever vegetations are discovered protruding into the trachea from the angles of the tracheal wound, they are to be treated as exuberant granulations would be in any other locality. They are to be destroyed by the application of caustics, or if they can be torn away their bases should be cauterized. Whatever operative procedure may be necessary to make them accessible to the required applications must be done, as their presence is always a source of danger. Whenever a prolonged use of the cannula is necessary, a watch should be kept for any signs of their development and their growth repressed from the first.

Chronic Hypertrophic Subglottic Laryngitis.—A chronic thickening of the soft parts between the vocal cords and the lower border of the cricoid cartilage is an occasional sequel to laryngeal diphtheria, and by the stenosis which it causes makes necessary the prolonged retention of a tracheal cannula. Attempts to relieve the obstruction by laryngotomy and excision of the obstructing tissues have been uniformly unsuccessful.

Care of the Cannula.—A constant watch over the cannula should be had from the moment of its introduction until either it is possible to remove it altogether, or the trachea has become accustomed to its presence and the tracheal secretions are normal. The surgeon must see that the nurse is thoroughly familiar with the mechanism of the double tube and knows how to remove and replace the inner tube with the least possible disturbance to the patient. It is especially desirable that the care of the cannula be entrusted to a judicious person who will not neglect it on the one hand, nor needlessly torment the patient on the other by useless fussiness over it. The inner tube should be removed only when there is a manifest occasion for it, as shown by some interference with the free passage of air. If the toilet of the trachea has been carefully made before the tube is introduced, the amount of expectoration will often not be very great during the first twenty-four hours; but if rapid breaking down of membrane, or a copious tracheal or bronchial catarrh coincides with the introduction of the cannula and occasions profuse expectoration, the tendency to clogging of the tube will be so frequently manifest that the removal of the inner tube and its cleaning will be required at comparatively short intervals. Even in cases which are not giving much trouble, obstructive crises are likely to develop suddenly at any time, caused by clumps of inspissated mucus, or pieces of exfoliated membrane, being driven into the tube by cough, or being brought up against its lower end so as to occlude more or less completely its opening. The extreme dyspnœa caused by such an accident, if not quickly relieved, will soon end in death. If the removal of the inner tube does not relieve the symptoms, the whole tube should be removed, and the needed measures to clear out the trachea be carried on through the unobstructed wound. When the inner tube is to be removed, the shield of the outer tube should be steadied by the thumb and forefinger of one hand, while the inner tube is disengaged and withdrawn with the other hand. The withdrawn tube should then be dropped into a cup of warm water, in which it should be left for a short time in order to soften the more or less inspissated mucus within it. Then a small mass of cotton-wool or a piece of sponge should be pushed through it, so as to clear it out. A splint from a broom will always be available for the purpose of pushing the cotton or sponge through, and is to be chosen rather than a wire or hairpin; for the latter, if not very carefully used, may scratch and mar the soft metal of which the tube is made. The tube having been cleaned out, it should then be rinsed in the water and replaced. The inner tube ought not to be left out any longer than is necessary to clean it, lest, when it is replaced, it push before it a possible mass of inspissated mucus, gathered on the inside of the outer tube while the inner one has been out, which by the time the tube is down in place may become a plug sufficient entirely to occlude it.

The outer tube may usually be left in place, without being disturbed, for the first two days. At the end of this time, that is, at the close of the second or the beginning of the third day, it will be desirable to remove the whole apparatus for the purpose of cleaning up. By this time the wound borders will have become somewhat firm, so that the opening down to the trachea will remain patent for a while without the tube, and sufficient time can be had to clean up the wound and the parts about, as well as to cleanse the tubes and arm them with fresh tapes. When the cannula is ready to be replaced, it will generally easily slip back into the trachea along the track which it has already made for itself, the walls of which are firm enough to guide the advancing end of the tube, if it is gently pushed along with proper regard to the direction which it should take. A hitch may occur when the end of the cannula reaches the entrance into the trachea, owing to the resilient cartilages having sprung back and partly closed the opening. If the tube has been kept out some time this obstacle is more likely to arise. Usually a little gentle pressure will overcome it, but care must be taken lest the tube be thrust down in front or at the side of the trachea instead of into it. The use of a conical-pointed pilot obturator (Fig. 4743) will always prevent any difficulty of this kind, and the surgeon would do well to be provided with one. The three-bladed dilator of Laborde is also very serviceable in overcoming such a difficulty. If the cannula track has not become quite well defined and firm, the hook retractors may be used to advantage for dilating anew the tracheal wound sufficiently to permit the cannula to pass.

If the walls of the wound are still so soft at this period that they fall together at once after removing the cannula, the wound must be kept open by a dilator while the necessary cares are given to it and a fresh tube is made ready for insertion. When this first change of the cannula is to be made the patient should be placed upon a table with the same arrangement as in the original operation, otherwise the surgeon may find himself at a very great disadvantage in his efforts to give the needed attention to his patient.

The further care of the cannula will differ according to the nature of the case for which tracheotomy has been done. If the tube is to be worn permanently, or until some cause of obstruction has been removed by subsequent operation, it will be left in place, with but rare changes. If the tube is one whose size and shape are adapted to the case, the trachea soon becomes accustomed to it so that it is borne without discomfort; the superficial wound heals rapidly, and the track of the cannula becomes a fistula with well-organized walls. If the operation has been done for the relief of temporary obstruction from inflammatory or diphtheritic disease of the larynx, it will be desirable to dispense with the cannula as soon as the obstruction shall have cleared away sufficiently to permit air again to pass through the larynx. To determine this the tube should be removed at the end of thirty-six or forty-eight hours, with great gentleness, so as to alarm the patient as little as possible, and the wound opening should be occluded with two or three folds of moist muslin placed over it, so as to test the ability of the patient to respire through the larynx. Frequently, even as early as this, it will be found that the obstruction has cleared away and that the cannula can be permanently dispensed with. If, however, respiration through the natural channels be found still impossible, the cannula must be replaced. Each day the permeability of the larynx may be again tested for a time. If by the eighth day it shall appear that easy respiration through the larynx is not yet possible, it will rarely be due to the persistence of obstructive exudate or œdematous swelling, but will be caused in the most cases either by temporary paralysis of the glottic dilators, diphtheritic in origin, or by glottic spasm of emotional origin; less frequently it will be due to persistent submucous inflammatory swelling or to inflammatory infiltration of the laryngeal muscles. More rarely yet, the inability to do without the tube will be due to the tracheal conditions already described, viz., in-turned cartilages, collapse of the trachea, or polypoid granulation excrescences. Cicatricial contractions causing stenosis of the trachea, following upon extensive destruction of its walls by ulceration or gangrene, may also oblige the patient permanently to retain the cannula. Whatever the cause, it will be well now to suspend for a time the efforts to do without the tube. A week may be allowed to pass during which the larynx is left at rest, and efforts are made to improve the general condition of the patient by iron and strychnine, and the local paresis by faradization. At the end of this time the efforts to dispense with the cannula should be renewed. All the manipulations should be made with gentleness, accompanied by manner and voice tending to reassure the patient, who has learned to rely on the cannula for breath, and who regards its removal with apprehension. As soon as any marked distress is caused by the absence of the tube it should be replaced, and further attempts deferred until another day. If after three or four trials suffocative crises continue to follow quickly after every attempt to remove the tube, these efforts should be desisted from again for some time, a week or more. In the vast majority of cases a time will finally come when the tube may permanently be dispensed with.

Emotional laryngeal spasm is a condition which has frequently to be encountered in the effort to remove the cannula in nervous, excitable children. It may coexist with and thus aggravate the difficulties caused by other conditions, or may be the sole trouble.

This emotional condition is to be overcome by tact, patience, and time. Many artifices have been resorted to for conquering the nervous fear upon which the spasm depends. Gradual shortening of the cannula, even down to the point of a mere button resting upon the closed external wound, and gradual narrowing of the cannula until it is no longer a pervious tube, have each been resorted to successfully. The confidence of the patient in his ability to breathe without the tube must be awakened; how to do this must be left largely to the ingenuity of the attendants and the inspiration of the occasion.

Lewis S. Pilcher.

TRAGACANTH.—(*Tragacantha*, U. S., Br., P. G.; *Gomme adragante*, Cod. Med.) A gummy exudation from *Astragalus gummifer* L., and from other species of *Astragalus* (fam. *Leguminosæ*). The species yielding this gum are straggling, spiny shrubs of southwestern Asia, some of them extending into southeastern Europe. The gum is a product of the mucilaginous degeneration of the cell walls of the pith. At certain seasons it is subjected to a great pressure within the stem, by which it is forced out, in the manner indicated in the accompanying illustration, through any opening reaching to the surface. Many such openings occur from natural causes, while others are made for the purpose by the gum collectors. The form of the exudate varies somewhat with that of the opening, so that cylindraceous ("vermicelli"), ribbon-like ("flake"), tear forms, etc., occur. Most of the flake form is obtained from artificial incisions. The gum is gathered promiscuously by the collectors, and is carefully assorted by professional pickers after being

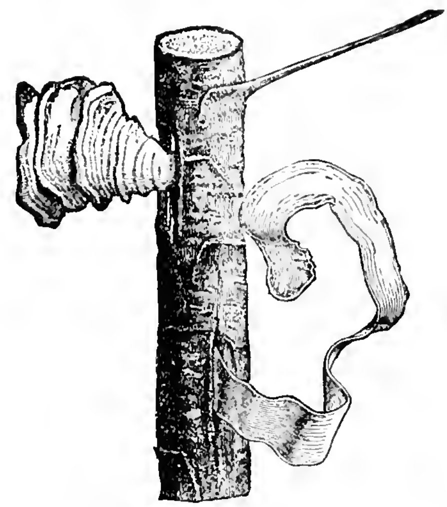

FIG. 4746.—Gum Escaping from Incisions in a Branch of a Tragacanth Shrub. (Baillon.)

marketed. There are numerous commercial grades, primarily designated by number, and depending upon the purity, solubility, and whiteness of the article.

DESCRIPTION.—In narrow or broad bands, more or less curved or contorted, marked by parallel lines or ridges, white or faintly yellowish, translucent, horn-like, tough, and rendered more easily pulverizable by a heat of 50° C. (122° F.).

On treating tragacanth with water, it swells and gradually forms a gelatinous mass, which is tinged blue by iodine T.S., and the fluid portion of which is precipitated on the addition of alcohol, but is not colored blue by iodine T.S.

Tragacanth consists of from one-third to one-half its weight of *bassorin* ($C_6H_{10}O_5$), an insoluble gum common to a number of commercial products (bassora gum, simaruba gum, cherry-tree gum, etc.) and of extended occurrence in the vegetable kingdom. It is capable of absorbing a good many times its weight of water, when it becomes transparent, soft, and jelly-like, but will not dissolve clearly when more water is added. Bassorin can be seen reasonably pure by putting a piece of tragacanth in a tumblerful of water and letting it remain, say, twenty-four hours until the soluble gum is dissolved out. About half of tragacanth consists also of a *soluble gum*, of the arabin series. Water, mineral substances, and impurities constitute the remainder. Tragacanth has no medicinal, and very little nutritive value. It is very largely used in the arts for sizing, mucilage, etc., and has considerable employment in pharmacy, where it is used as a basis of emulsions, for the suspension in liquid of powders and insoluble substances in "mixtures;" as a body for troches, etc. It appears in the following official preparations: *Trochisci Acidi Tannici*, *Trochisci Ipecacuanhæ*, *Trochisci Potassii Chloratis*, *Trochisci Santonici*, *Trochisci Zingiberis*, all of them belonging to the United States Pharmacopœia. There is a Mucilage of Tragacanth (*Mucilago Tragacanthæ*, U. S. P.) consisting of six parts of tragacanth, eighteen of glycerin, and enough water to make a hundred; this, diluted with about as much more water, will emulsionize cod-liver or castor oil sufficiently well; the usual strength is to make the emulsion one-half oil. It may be flavored with peppermint, almond, or other fragrant substance. For desk purposes, as an adhesive mucilage, tragacanth, softened with thymol water and kept from evaporation, will not decompose or sour in the least, even after years.

W. P. Bolles.

TRAINING, PHYSICAL.—The word *training* has two applications in common use. Its more general application is to a system of exercises intended to develop the neuromuscular system. In this application physical training is used in the literature of the subject as synonymous with "*physical education*" and "*physical culture*." The other application of the word *training* is to a specially devised daily programme of exercise and diet preparatory to an athletic contest.

I. PHYSICAL TRAINING.—Physical training in its general sense is an educational system supposed by many to signify the development of muscle alone, but it became apparent very early in the study of muscular development: (1) that there could be no extensive development of muscles without brain development; and (2) conversely no extensive development of the brain as a rule without at least a moderate muscular development. As soon as educators became cognizant of the intimate relation between brain development and muscular development, the far-reaching importance of a carefully worked out system of physical education became generally recognized. Germany, Sweden, and England as a result of the efforts of Jahn, Ling, and Maclaren, respectively worked out in those countries systems represented at the present time by the German method in the Turn Verein, the Swedish gymnastics, and the English modification of the German system.

Somewhat later, Dr. Dio Lewis started a movement in this country through his lectures and writings on hygiene, muscular exercise, and gymnastics. The general interest aroused led to the gradual development of a system which embodies some of the better features of the European systems, while introducing many features which are particularly adapted to the conditions that exist in America.

The system of physical training, now used in this country, may be classified under the heads: (1) Developmental or educational; (2) corrective or therapeutic; (3) recreative or hygienic.

1. *Developmental* or *educational* physical training is a progressive series of physical exercises designed to cultivate in the growing child or the youth muscular strength and the ability to command the muscles singly or in groups to act gracefully and accurately. Both grace and accuracy depend upon co-ordination. Such a series of exercises is adapted not only to the development of the normal child, but also of the child whose mental and physical development has been retarded or arrested.

2. *Corrective* or *therapeutic* physical training consists of a series of specially devised exercises prescribed by a physician to correct special pathological conditions.

3. *Recreative* or *hygienic* physical training consists of a series of calisthenics, gymnastic floor games, field sports, and athletics intended to maintain the physical vigor, to divert the mind from its regular channel, and to increase the power of resistance to disease.

II. ATHLETIC TRAINING.—1. *Definition.*—To produce in an individual by a definite régime a condition of strength, agility, skill, and courage; with ability to endure pain, to maintain self control, to resist or quickly to recover from fatigue.

2. *The régime* of training consists in a course of carefully arranged exercises or tests which gradually bring the muscular strength and agility to their highest point of perfection. The exercises are of a threefold character: (*a*) General exercises to increase general strength, and particularly the strength of heart and capacity of lungs, as upon a vigorous circulation and an ample respiration depends much of the success of the athlete in these contests. (*b*) Daily practice in the event or particular exercise in which the athlete is to contest. The object of this part of his training is to give him skill and courage in that particular exercise or sport. (*c*) A carefully arranged system of diet, baths, and general hygiene, the object of which is to keep his system in the best possible hygienic condition.

TRANSFUSION.—Under this title are included the various processes of introducing into the veins of a patient the blood of another person or of an animal. The term is often used more broadly to include also the procedures already described under the titles *Hypodermoclysis* and *Intravenous Injections.*

The possibility of transfusing blood was known to the ancients and was occasionally practised during the Middle Ages. A famous instance is that of Pope Innocent VII., mentioned by Savonarola. The pope was bled and his blood injected into two young men. They were bled in turn and their blood was introduced into the veins of the pope. All three died.

After the discovery of the circulation by Harvey in the early part of the seventeenth century a number of experiments on animals and on man were done with the object of treating various diseases by the transfusion of blood. Attempts were made to cure leprosy, insanity, and other diseases in this way, as well as to combat hemorrhage and shock and to rejuvenate the aged. The names of Libavius, Lower, and Denis are prominent in this connection. They had more or less success In consequence of the death of one of Denis' patients, treated for insanity by the introduction of lamb's blood, the operation was forbidden in France. It was revived in the early part of the last century. It then steadily gained ground as its value became obvious. Only quite recently has it been displaced by the safer, simpler, and equally efficacious method of saline infusions.

The blood of animals and of man has been employed. Many of the early operators used the blood of lambs. The introduction of the blood of an animal of one species into the veins of an animal of a different species is, however, a dangerous procedure, as the blood of one animal destroys the corpuscles of another. Moreover, in man marked toxic symptoms are produced. Even with small doses dyspnœa, sensations of heat and distention, especially in the face and head, backache and headache may come on during the administration. Increased peristalsis with abdominal pain, vomiting and catharsis may occur. In the course of an hour chills and fever are almost always observed. Subsequently hæmoglobinuria, albuminuria, and urticaria are sometimes present.

Defibrinated human blood has also been used. This is objectionable because the process is somewhat complicated and time-consuming, and it is difficult to keep the blood aseptic. A more important objection arises from the fact that the fibrin ferment is formed in the process of defibrination, and is present in the blood injected. There is good reason to fear that intravascular clotting might result.

The immediate transfer of blood from donor to patient without intermediate manipulation is probably the best method. Even this, however, is not free from the dangers of air emboli and of clot formation in the tubes. It is possible, too, that serious diseases might be transmitted. Another objection is the difficulty of securing a donor. These objections are not, however, insurmountable, and the operation has been developed to such a point of safety and convenience that, had not safer and simpler, but almost equally efficient means been devised for accomplishing the same end, there can be no doubt that the operation would be of great value to-day.

Operative Procedures.—These have varied greatly, but in the present status of the operation a detailed description is not necessary. For further details the reader is referred to the excellent article by Dr. Howe in the first edition of this Handbook. For direct transfusion the apparatus of Aveling is perhaps the best. This consists of a rubber tube eighteen inches long, with a small bulb in the middle and a cannula and stopcock at each end. The instrument is boiled, filled with warm, sterile decinormal salt solution (sodium chloride, six-tenths of one per cent.), and every care taken to expel all the air from it. It is kept, while the patient is being prepared, in a basin of the same solution. The arm of the patient is rendered surgically clean, and the most prominent vein near the bend of the elbow is exposed by a short incision and slight dissection. The vessel is opened and one of the cannulæ inserted. The assistant in the mean time has inserted in exactly the same manner the other cannula in a vein of the donor. The latter should be in good health, of strong mental equanimity, and preferably not an anxious relative of the patient. As in phlebotomy the veins may be made more prominent by applying about the arm above the elbow a bandage tight enough to obstruct the venous outflow without stopping the pulse. During the transfusion the bandage should of course be removed from the patient, but may with advantage be left upon the donor.

The cannula in the donor should point toward the fingers, that in the patient toward the shoulder. They

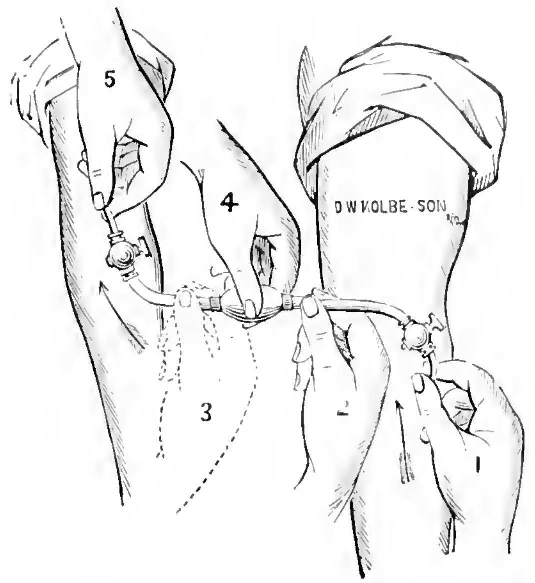

FIG. 4747.—Aveling's Transfusion Apparatus. 1, 5, Hands of the assistant holding the cannulæ in position; 4, hand of the operator compressing the bulb; 2, 3, hand of the operator compressing alternately the afferent and efferent tubes.

need not, as a rule, be tied in. The operator now pinches the tube between the bulb and the donor (*2*, Fig. 4747), and with his other hand opens both stopcocks. He then compresses the bulb, thus driving its contents into the patient's arm. Keeping the bulb compressed, he removes the first hand and pinches the tube on the patient's side of the bulb (*3*, Fig. 4747). Now, the pressure on the bulb itself being released, the apparatus fills with blood from the donor, which, on repeating the process, is forced into the patient's vein. Five to ten ounces of blood should be transfused. The quantity can be calculated from the capacity of the bulb, ordinarily two drachms.

It is said that the bulb is unnecessary as, by properly bandaging the arm of the donor, his intravenous blood pressure may be made sufficient to bring about the transfer.

For the use of defibrinated blood various methods were devised. The simplest way is as follows: The donor is bled into a clean vessel. The blood is then whipped with glass rods till the fibrin is all removed. It is then strained through muslin and kept warm until needed by setting the container in warm water. An ordinary glass funnel with a rubber tube ending in a cannula and guarded by a stopcock may be used for the injection. Syringes of various sorts have been used both with whole and with defibrinated blood. Full aseptic precautions should of course be observed and every care taken to exclude air bubbles.

Peritoneal transfusion, the injection of blood into the peritoneal cavity, is of no practical value and should not be used. *Autotransfusion* consists of increasing the supply of blood to the essential organs at the expense of the limbs. It is accomplished by the application of tight rubber bandages to the legs, beginning at the toes and going upward. It is of undoubted value for temporary use in emergencies where large amounts of blood have been lost, until the volume of the circulation can be made up in other ways. A somewhat similar procedure has been recently advocated for the purpose of maintaining the blood pressure in cases in which the vaso-motor centre has been exhausted by shock—the pressure being applied to the abdomen and extremities by inflating a pneumatic rubber suit.[1]

The principal indication for transfusion is severe hemorrhage. It may be said that in most cases the introduction of salt solution under the skin will be sufficient. Occasionally, where the absorption of such an injection does not take place or where every instant of time is of value, the intravenous route is to be selected. Rarely, if ever, will there be enough advantage in the use of blood to overbalance its greater dangers and difficulties, and the greater delay in administering it.

The repeated intravenous injection of small quantities (5–25 c.c.) of defibrinated lamb's blood has been advocated by Bier[2] for the purpose of bringing about the reactions described in a previous paragraph in cases of old, chronic tuberculosis. Some of his cases were encouraging. *Ralph C. Larrabee.*

TRANSPORTATION OF THE DISABLED ON LAND.—The first systematized methods for the care of the wounded in battle and their removal from the field date from 1792, when Baron Larrey, chief surgeon of the French army under Napoleon I., established his system of *ambulances volantes*, or flying field hospitals. Shortly after, in 1800, Percy, another distinguished surgeon of that army, organized companies of *brancardiers*, or stretcher-bearers, whose duty it was to remove the wounded from the battlefield to a place of safety, where they could receive proper care.

Since that period increasing attention has been paid to this subject, until at the present day more or less elaborate systems of military hospitals, and means for transporting the sick and wounded to these hospitals are maintained by all civilized armies.

It should be explained in this connection that in foreign armies by the term "ambulance" is understood the entire movable field hospital, including medical and surgical supplies, the means of transportation, the animals and harness, and the personnel of the hospital officers and men of the sanitary force. In our army the term is restricted to the *ambulance wagon*, in which the sick and wounded are carried. The term ambulance corps in the United States Army comprehends the ambulance wagons, litters and other appliances for transporting the disabled; the baggage and subsistence wagons; the harness and animals, as well as the officers and men who are charged with their control and management. In this article the terms will be used in the same sense in which they are understood in the United States.

In our service the means of transportation, which usually accompany a moving command, are its ambulances

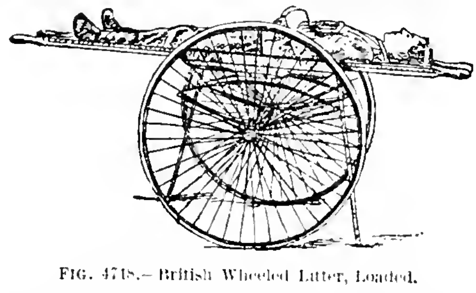

FIG. 4748.—British Wheeled Litter, Loaded.

and hand litters. At times, owing to the character of the country in which the troops are operating, as in regions without roads, the ambulances cannot be employed; in such cases other means must be resorted to. When, owing to excessive casualties or other exigencies, sufficient ambulances are not available, army wagons, wagons or carts of the country, saddle, pack, and draught animals may supplement the ambulances. When rail or water transportation is available and practicable, railroad trains and boats are employed, especially when large numbers of sick and wounded are to be removed to a considerable distance, as in the service of evacuation. It is a military principle that the operating force should not be embarrassed by the care of its sick and wounded any longer than necessary; this enables the field hospitals, which always accompany the moving army, to travel light, makes room for the wounded from an impending engagement, and diminishes the danger of infecting the well by those already diseased. Besides, base and general hospitals being more or less permanent institutions, are better supplied with the necessities and comforts for the care of the sick than would be possible in a hospital which accompanies a moving force.

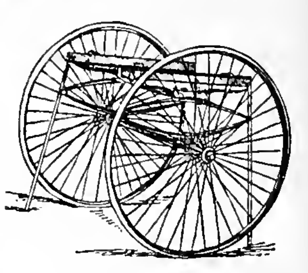

FIG. 4749.—British Wheeled Litter, without Litter.

Ordinarily patients from the battlefield will have to be carried on litters to the dressing station, from which point they are again carried by litters to the ambulance stations; here they are loaded into the ambulances for removal to the field hospitals. Other specially devised means that are used for the transportation of the disabled in the military service are the wheeled litter, cacolet, single or double-horse (or mule) litter, and the travois.

The hand litter has already been described in this work in the article on *Army Hospital Corps* by Major Bushnell, and will not be considered here.

The Wheeled Litter.—The wheeled litter is simply a litter mounted upon wheels, usually two in number, designed to be propelled by a single bearer. Numerous different patterns of such appliances have been devised, varying in design with the character of the service required of them. In some forms the bed for supporting the patient is removable, permitting of its use as a hand litter; in others, it is fixed permanently to the carriage; some are made to fold into a compact bundle to permit of ready packing or shipment; in another form, the litter is mounted between two bicycles, which are joined to the litter frame and to each other by interlocking bars; tricycles arranged "fore and aft" with reference to the litter have also been adapted to form the carriage. The simplest and most practical form consists of two light wheels and an axle, supporting a frame for the litter with a device for holding it in the horizontal position when at rest without the bearer's help. This device consists of two hinged bars of proper length fastened to each end of the frame or carriage, which are swung up and secured by suitable fastenings when the litter is in motion. Usually litters of this class are covered with a removable hood and are mounted upon springs. An excellent type was used by the British military surgeons in the recent war in South Africa, and is shown in Figs. 4748 and 4749. The wheels have steel spokes and rims, rubber tires, and ball bearings; the bed is made to take the British regulation litter, and is mounted upon elliptical springs; the litter is securely held in place upon the bed by means of two buttons with tightening screws. The great object of this carriage is said by its designer, Major McCormack, R.A.M.C., to have been "to obtain mobility, strength, and lightness combined with efficiency and a ready and easy means of transport for sick and wounded, no matter where a patient has to be transported from." Nevertheless, wheeled litters have but a limited range of usefulness. They were extensively tried during our Civil War for the purpose of removing the wounded from the battlefield, but did not meet with favor from our surgeons; they proved to be practically useless over the rough ground upon which battles were fought. In moving patients from one part of a hospital to another, and in villages and towns where ambulance systems do not exist, their utility is undoubted; but in the military service their sphere of usefulness will be largely confined to work in and about hospitals, and in loading and unloading trains; they will here prove economical of men and comfortable to patients.

Horse-litters.—One form of horse-litter is the *cacolet*, which consists of a pack saddle, from each side of which

FIG. 4750.—British Crimean Cacolet. (After Weir.)

is suspended a seat or chair; in this seat the patient is carried in the sitting posture. This form of litter was extensively used by the English in the Crimean war, and by the French in Algeria and Mexico, apparently with satisfactory results. In our service trials were made during the Civil War with this form of litter, but the consensus of opinion of our medical officers, who had experience in its use, was decidedly against this method of transportation for sick and wounded. No doubt this unfavorable opinion was largely due to inability to secure properly trained animals, and perhaps also to the fact that other more satisfactory means were available.

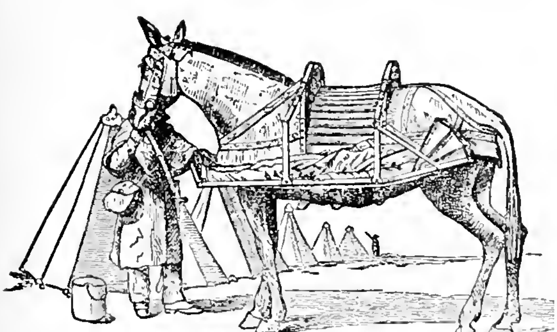

FIG. 4751.—British Crimean Mule Litter. (After Weir.)

Its sphere of utility should properly be confined to work over country that is inadmissible to wheeled transportation. Its successful employment requires strong, docile and well-trained animals, and a comparatively open country; it cannot be employed on a narrow trail running through a heavily wooded region. Fig. 4750 represents the cacolet used by the British in the Crimea.

During the same war the British also made successful use of a mule-litter in which a litter is slung horizontally from each side of a pack-saddle. Like the cacolet, this form of litter has not been favorably considered by our medical officers, and the same objections hold good with reference to it. An additional objection is its weight, which, with its pack-saddle and bedding, is placed at one hundred and sixty-seven pounds; this, added to the weight of two patients, makes a formidable load for the average-sized horse or mule. Fig. 4751 illustrates the arrangement and general appearance of this kind of horse-litter.

In another form of horse-litter a single patient is carried in the recumbent or semirecumbent position upon the back of the animal, either upon a specially devised saddle and litter, or upon an improvised arrangement made by securing the ordinary hand-litter to a pack or riding saddle. An example of the former is the McElderry single mule-litter (Figs. 4752 and 4753), devised by the late Major Henry McElderry, Surgeon, U.S.A., with a view to its employment in operations against the Modoc Indians in the lava beds of California. In this, the frame is hinged, allowing its adjustment at different angles; the hinges also permit it to be folded compactly

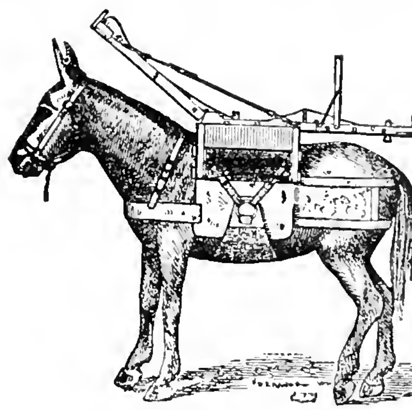

FIG. 4752.—McElderry's Single Mule-litter.

together for facility in its transportation. The saddle to which it is attached when in use is that known as the Mexican *aparejo*, now universally used in pack-trains. Some of the advantages claimed for it by its inventor are that "it is especially adapted for use in broken and mountainous country; long narrow and winding defiles, abounding in sudden and abrupt angles; and in places and under circumstances generally where no other kind of litter could be employed. A wounded man can be transported on this litter with entire safety on the back of any steady pack-mule or horse, taken indiscriminately out of the pack-train; the animal not requiring any special training before he will pack it, otherwise than that already received in the pack-train."

In the improvised form two stout wooden traverses are strongly lashed to the pommel of a riding or pack-saddle, preferably a pack-saddle; upon the outer ends of these traverses two wooden poles or bars are fastened in a longitudinal direction and parallel to each other, forming a framework upon which the litter rests and to which it is securely bound by ropes or other lashings.

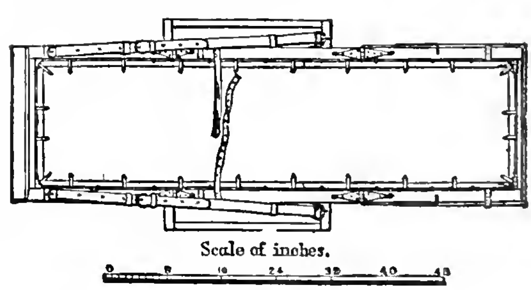

FIG. 4753.—Plan of McElderry's Single Mule Litter.

The patient is carried in the recumbent posture with head toward the head of the animal. In this form of transportation but little lateral oscillation is experienced, though the jolting must be considerable. It is espe-

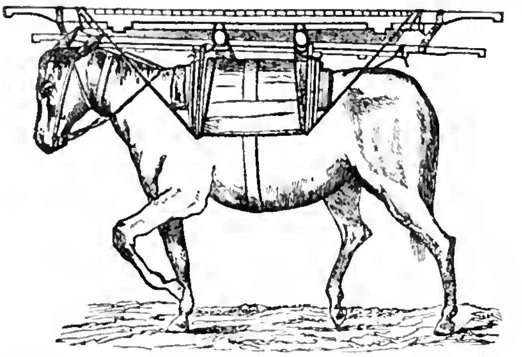

FIG. 4754. Single Mule Litter used by the French in Mexico. (After Gouchet.)

cially adapted to mountainous regions where trails are narrow and the surface of the ground is broken. It is not economical of attendants, as in addition to the man who leads the animal one is necessary to keep the patient from slipping off in going up and down steep places. This method was used by the French in Mexico, through a mountainous country over long distances, and it is reported that the patients bore the journey very well, though complaint was made of the pressure of the forward bow of the saddle upon the patient's back. This was remedied by shifting his position or by using some kind of padding to increase the thickness of the bed at that point. Fig. 4754 represents the method then used. This adaptation is admirable in principle, and can usually be improvised from materials at hand.

The transport of sick and wounded by means of the *two-horse-litter* has commended itself to our military surgeons, and has been frequently employed in campaigns against Indians in the United States and in operations in the Philippine Islands. In this method a litter is suspended between two horses or mules in tandem; it is easily extemporized where suitable materials are at hand. In its construction two stout poles about sixteen feet and a half in length are required, and two cross pieces, about three feet long, which serve as traverses to keep the poles apart. The traverses forming the ends of the litter bed are fastened five feet from the front and rear ends of the poles; between them a piece of canvas, a blanket, or other suitable material is stretched and securely fastened to the sides of the poles and cross pieces. Sick and wounded men can be safely and comfortably carried over long distances by this form of litter. The objections to it are that two animals, and at least two attendants, are required for one patient, and that it cannot be employed upon narrow paths with short turns and steep declivities. At one time (1861) horse-litters of this pattern were regularly issued in our army to "posts whence they may be required for service on ground not admitting the employment of two-wheeled carriages." In these the poles were hinged to permit their packing on pack-animals; the complete litter with straps and girths weighing 88 pounds. These litters are still recognized as means of transport; paragraph 1614, Army Regulations, 1901, authorizes their issue upon recommendation of the chief surgeon, though the writer is not aware that they have been so issued in recent years. In the improvised form they have been recently employed in the Philippine Islands (see Fig. 4755).

Another form of horse-litter, more economical of men and animals, is the Indian travois. This contrivance was in universal use by the North American Indians for the transportation of supplies and other property as well as for carrying their disabled. In this form the front ends of the litter poles are fastened to the sides of the animal like the shafts of a wagon; the rear ends drag upon the ground. One pole is slightly shorter than the other, in order that in passing an obstacle the shock may be received successively by each end and the motion be equably distributed. The travois is now recognized as a regular means of transport for the disabled in our service. The Medical Department Regulations for 1902 direct that ambulances Nos. 1 and 5 in each ambulance company shall carry a travois. Paragraph 148, Drill Regulations for the Hospital Corps, 1902, gives the following instructions for improvising this kind of litter:

"A travois may be improvised by cutting poles about 16 feet long and 2 inches in diameter at the small end. These poles are laid parallel to each other, large ends to the front, and 2½ feet apart; the small ends about 3 feet apart, and one of them projecting 8 or 10 inches beyond the other. The poles are connected by a cross bar about 6 feet from the front ends and another about 6 feet back of the first, each notched at its ends and securely lashed at the notches to the poles. Between the cross pieces the litter bed, 6 feet long, is filled in with canvas, blanket, etc., securely fastened to the poles and cross bars, or with rope, lariat, rawhide strips, etc., stretching obliquely from pole to pole in many turns, crossing each other to form the basis for a light mattress or improvised bed; or a litter may be made fast between the poles to answer the same purpose. The front ends of the poles are then securely fastened to the saddle of the animal. A breast strap and traces should, if possible, be improvised and fitted to the horse. On the march the bearers should be ready to lift the rear ends of the travois when passing over obstacles, crossing streams, or going uphill."

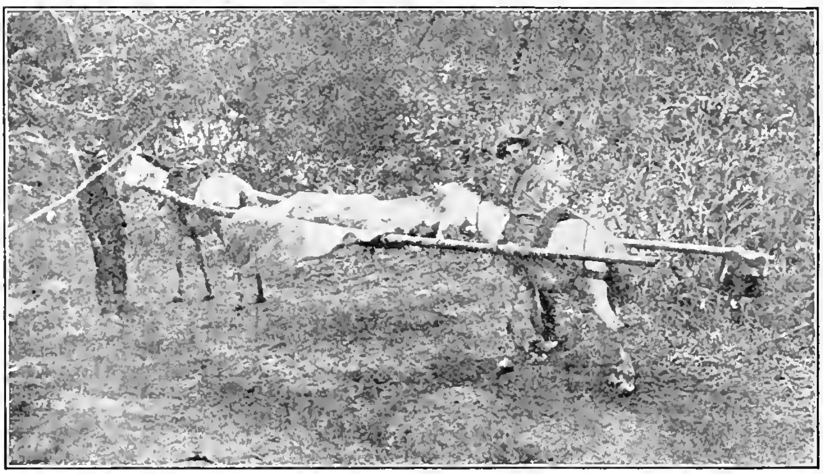

FIG. 4755.—Improvised Two-horse Litter, as used in Philippine Islands.

Colonels Greenleaf and Cleary, of the Medical Department of the United States Army, have each devised a travois which can be used either as a hand-litter or as a horse-litter. In both the shafts are made detachable, being attached to the side poles of the litter proper by means of collars and pins; both can be rolled up, making them easy to transport in wagons or upon pack-animals. Lieutenant-Colonel Havard, Deputy Surgeon General,

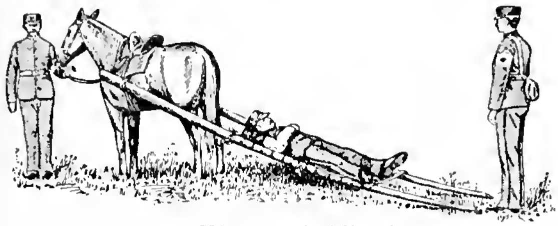

FIG. 4756.—Improvised Travois.

U.S.A., has more recently suggested that this form of litter could be further perfected by making the rear ends of the poles rest upon a narrow two-wheeled truck instead of dragging upon the ground.

The travois, in the absence of ambulances or other wagons, has proved to be a very satisfactory method of transportation by animals. It is comfortable, safe, easily improvised, and can be employed over rough and mountainous country where other methods of animal transportation are not feasible, as well as over level country. Upon a fairly level road the two-horse litter is probably preferable, and in the case of a fractured limb, there is less liability of disturbance of the fragments, as in this mode of transport the patient is carried in a horizontal position. For general utility and especially where economy in men and animals has to be considered, the travois will be found superior. Medical officers who have had experience with them look upon them with favor, and Havard has wisely suggested that two, to be carried by pack-mules to the front, be provided for each regiment in the field under circumstances where ambulances are not available. Fig. 4756 shows an improvised travois in its simplest form. In all these forms of litters intended to be drawn or carried by animals mules are generally to be preferred to horses, in that they are patient, more quickly trained, surer-footed, and accustomed to carry burdens.

Devices intended for attachment to the saddle, with the object of supporting a sick or wounded man upon a

FIG. 4757.—The Improved Army Ambulance, Pattern of 1900.

horse, have been suggested at various times; but on trial all such arrangements have been found to be impracticable. If necessary to support a disabled man on a horse, a comrade mounted behind him will answer the purpose, or a lean-back made of a blanket-roll, a bag stuffed with grass, or a sapling bent into an arch over the cantle of the saddle, may be secured to the saddle and the patient bound to it.

The Ambulance.—The requirements of a good military ambulance are that it shall be of sufficient structural strength, due regard being had to lightness, to withstand the rough usage to which it is liable in active service; so constructed as to permit its turning in a space equal to its length; it should be able to travel over rough, sandy, or muddy roads; comfortable to its occupants when partially as well as when fully loaded; capable of carrying patients both in the recumbent and in the sitting position; it should have provisions for carrying small quantities of dressings, food, stimulants, water, and patients' effects, without intruding upon its carrying capacity for patients; also so designed as to permit rapid loading and unloading. The present pattern of the United States Army ambulance (Fig. 4757, pattern of 1900), known as a Munson's modification, has been evolved from the older types and fulfils these requirements. It is an excellent wagon and possesses features that are found in no other military ambulance. It is a four-wheeled vehicle intended to be drawn by either two or four horses; the body is 9 feet long and 4 feet 7½ inches

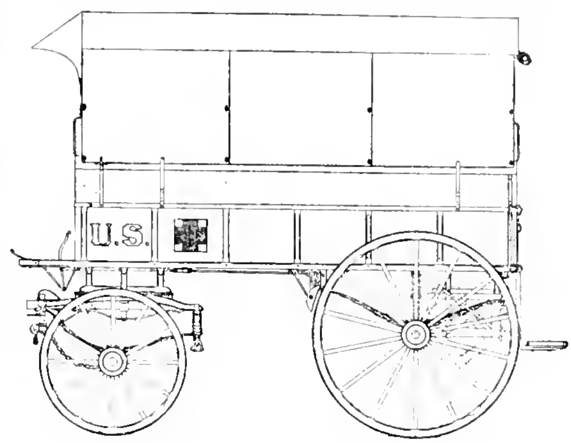

FIG. 4758.—Side View of Improved Army Ambulance.

wide, outside measurements; the height of the floor is 3 feet 8 inches above the ground. The space for patients is 7½ feet long and 4 feet 4½ inches wide; in front of this space is the driver's seat, wide enough for three occupants; under the driver's seat is a box 4 feet long, 10 inches wide and 16 inches high, for storing extra parts and other articles. The body is covered by a wooden roof supported by wooden bows; the height of the roof in its centre is 5 feet from the floor; the sides and rear end are provided with curtains, which can be rolled up; a division curtain, which also is made to roll up, extends across the wagon just back of the driver's seat; all curtains are made of pantasote; the roof is likewise covered with this material. At the rear is attached a step 2 feet above the ground; the rear of the body is closed by a tail-gate. The body is swung on

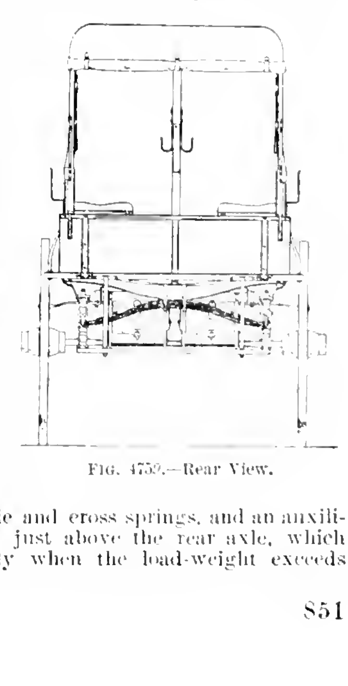

FIG. 4759.—Rear View.

the axles by both side and cross springs, and an auxiliary spring is placed just above the rear axle, which comes into play only when the load-weight exceeds

400 pounds. The ambulance is provided with an efficient foot brake, operated by the driver; the brake lever passes through the centre of the footboard and is furnished with a ratchet which engages in a rack

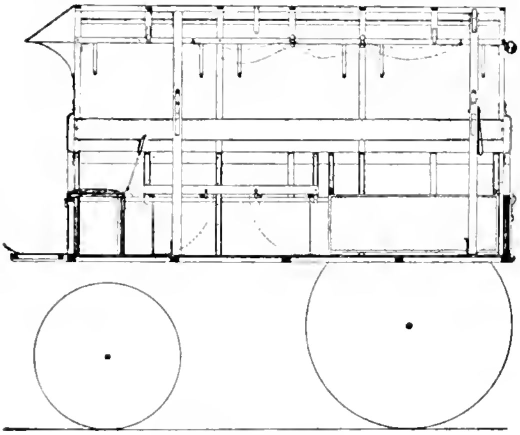

FIG. 4760.—Vertical Section.

in the footboard. The diameter of the hind wheels is 4 feet 2 inches, of the front wheels 3 feet, exclusive of the tires; tires are of steel, 2¼ inches wide and $\frac{7}{16}$ of an inch thick; the track of the vehicle is 5 feet 2 inches over rims. Two cylindrical water tanks, 15¼ inches long, 10¼ inches in diameter, made of No. 22 galvanized iron, each provided with a compression bibcock, are suspended in stout wooden frames from underneath the body, just behind the rear axle; each tank has a capacity of 40 litres. The interior of the ambulance is fitted with four removable seats, two on a side, which, when not used as such, are hung against the sides. The cots are regulation hand-litters, four of which are carried by each ambulance. When used to carry recumbent cases two litters rest upon the floor; the other two are suspended by hooks and straps from the litter-supporting posts and the curtain rails respectively, 27 inches above the floor. The use of the hand-litter, instead of a special cot, allows the patient to be loaded into the ambulance without being transferred from the litter, upon

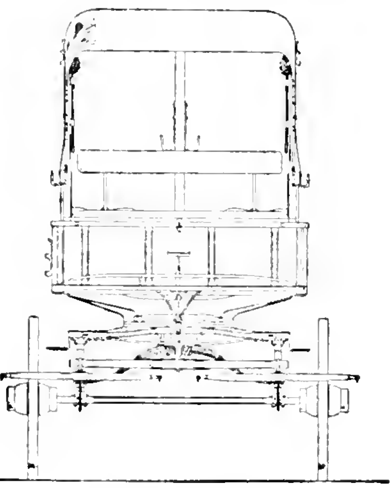

FIG. 4761.—Front View.

which he is carried to the wagon. The litter-supporting posts are wooden uprights, 3 inches square, placed 73 inches apart; the front post is placed 1 foot behind the driver's seat, and is stationary, being secured to the roof and floor; the one at the rear is hinged at the top; when the upper berths (litters) are not to be used, it is strapped to the roof. When the upper berths are to be used, it is unstrapped, swung into a vertical position, and its lower end is secured to the floor by means of an iron shoe and bolt. Upon each side of the litter-supporting posts is a hook for the support of the inside handles of the litter, and opposite each hook, fastened to the inside of the curtain rail, is a strap to hold the outside handles. A hammock net is also fastened by hooks to the inside of the curtain rail on each side; these are for carrying clothing or equipments of the patients. This ambulance will carry patients either recumbent or sitting up, or both classes of patients together, viz., 12 sitting, or 2 recumbent and 6 sitting, or 4 recumbent. Figs. 4758, 4759, 4760, and 4761, show the general plan of construction of this vehicle.

In most of the European armies ambulances are accompanied by light carts, which carry dressings, drugs, foods, etc.; in our service these articles are carried by each ambulance as follows:

CONTENTS OF AMBULANCE BOX OF HOSPITAL STORES.

(In metal box, packed in rectangular galvanized-iron boiler with lid, enclosed in iron fire grate, carried under body of ambulance.)

Arrowroot	pounds,	2
Beef, soluble liquid, or extract, in 100 c.c. containers	containers,	6
Brandy, in 500 c.c. bottle	bottle,	1
Can opener	number,	1
Chocolate, sweetened	pounds,	3
Condensed milk, unsweetened, in commercial tin	tins,	6
Malted milk	pounds,	2
Matches, safety in waterproof tin	boxes,	2
Pepper, black, ground, in dredge with screw cap	ounce,	1
Salt, in dredge with screw cap	ounces,	3
Sugar, white, granulated	pounds,	3
Tea, black or green	pound,	½

CONTENTS OF AMBULANCE BOX OF SURGICAL DRESSINGS.

(In metal box, packed in rectangular water boiler with lid, enclosed in iron fire grate, carried under body of ambulance.)

Antiseptic tablets, 125 in 125 c.c. bottle	bottle,	1
Bandages, plaster of Paris, two-inch	number,	6
Bandages, roll, sterilized, gauze, two one-half-inch	number,	24
Chloroformum, in 125-c.c. bottle	bottle,	1
Cotton, absorbent, in 30-gm. package	packages,	12
First-aid packets	number,	24
Gauze, iodoform, sterilized, 0.5 metre in package	packages,	12
Gauze, plain, sterilized, two 0.5 metre pieces in package	packages,	20
Morphinæ sulphas, 8-mgm. hypodermic tablets	tubes,	8
Pins, safety	dozen,	4
Plaster, adhesive, in roll 30 cm. wide	number,	2
Strychninæ sulphas, 1-mgm. hypodermic tablet	tubes,	8

SPARE PARTS AND ADDITIONAL ARTICLES CARRIED BY EACH AMBULANCE.

Axle grease	pot,	1
Boilers, galvanized iron, with lid	number,	2
Bolt, king, extra	number,	1
Brush, horse	number,	1
Bucket, galvanized iron	number,	1
Color, camp	number,	1
Comb, curry	number,	1
Dressings, surgical, in metal box	box,	1
Grates, fire, iron	number,	2
Guidon, ambulance	number,	1
Hatchet	number,	1
Hospital stores in metal box	box,	1
Lamps, ambulance	number,	2
Lanterns, extra, one white, one red, in space under seat	number,	2
Lantern wicks, extra	number,	6
Link, split	number,	1
Litters, hand	number,	4
Oil, mineral, in space under seat	tin,	1
Tanks, water	number,	2
Whip	number,	1
Wrench, monkey	number,	1

NOTE.—In addition to the above, ambulances Nos. 1 and 5 will carry an extra pole and a travois.

The allowance of ambulances for troops in active service in the United States Army is estimated upon a basis of one ambulance to 400 men of the effective force. Three ambulance companies, usually one company to each brigade, are ordinarily attached to each division of normal strength; nine ambulances is the number prescribed for each company. For a battery of artillery, detachment of infantry, or squadron of cavalry, operating independently one ambulance is allowed. The strength of the armies of the United States in time of war is not fixed either by statute or by regulation; hence a division may be composed of a variable number of troops. Usually it has consisted of three brigades of two or three regiments to the brigade, varying accordingly between 12,000 and 18,000 men; upon a basis of one ambulance to 400 men, the division ambulance corps should contain 30 to 45 ambulance wagons. Havard recommends as a basis 3 ambulances to 1,000 combatants, and in his scheme of organization provides for 12 ambulances to each ambulance company, assuming the strength of the division at about 11,000 men. Reynolds recommends 15 to each company,—the division strength being assumed at about 13,000 men. It is difficult to estimate even approximately how much ambulance transportation should be provided for wounded after a battle of magnitude between forces equally well-armed with modern firearms. Recent experiences have shown that the ratio of wounded to the strength engaged is not far from 12 per cent. With a division of 12,000 to 18,000 men this would give 1,440 to 2,160 wounded; probably one-third of this number would not require ambulance transportation, while about 1 in 12 would be so seriously wounded as to make their immediate transportation beyond the dressing station inadvisable; excluding these, there would remain 880 wounded for a division of 12,000, and 1,320 for a division of 18,000, for whom ambulance transportation would be required. The present model of regulation ambulance would probably average 8 men per trip, and with the field hospitals situated near enough to permit each ambulance to make 4 trips, 28 to 40 ambulances would be needed for a division of the strengths mentioned. It must not be understood that the allowance laid down by Medical Department regulations is inflexible; it simply serves as a basis, and may be changed as the exigencies may require.

The following regulations for ambulance drill are those prescribed for the present pattern of ambulance, as laid down in the "Drill Regulations and Outlines of First Aid for the Hospital Corps, United States Army, 1902":

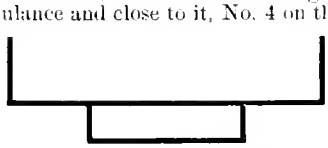
AMBULANCE DRILL.—The litters are said to be *packed* when they are strapped and placed upon the brackets. The seats are said to be *prepared* when they are horizontal, supported by the legs; and *packed* when they are hooked against the sides of the wagon.

To take posts at ambulance.

Being in line:

1. *At ambulance;* 2. POSTS.

The designated squad marches in a column of files to the ambulance; when No. 1 takes post on the left, No. 2 in the centre, and No. 3 on the right of the rear of the ambulance and close to it, No. 4 on the right of No. 3.



1 2 3 4

In the case of a litter lowered in rear of ambulance preparatory to loading, head of patient toward it, at the command *posts*, each number faces about and proceeds directly to his post.

This is the invariable position of the squad *at ambulance posts;* it may be taken from any position (the litter, if any, being *grounded* or *lowered*), and when disarranged, from whatever cause, the squad may be reassembled by these commands for service at the ambulance.

The ambulance having seats *packed* and the squad being *at ambulance posts:*

1. *Prepare;* 2. SEATS.

Nos. 1 and 3 raise the curtain, if necessary, and open the tail-gate; Nos. 2 and 3 enter the ambulance, No. 2 facing the front and No. 3 the rear seat of their respective sides. Each man seizes the lower edge of the seat about six inches from the ends with both hands and lifts it; he lowers the legs and adjusts them to the floor and tries the seat for firmness before leaving it. He then prepares in like manner the opposite seat. No. 3 unfastens the litter-supporting post and swings it to the front of the ambulance, where it is grasped by No. 2, who lifts it to its place and straps it. Nos. 3 and 2 now resume their positions *at ambulance posts.*

The ambulance having seats *prepared*, and the squad being *at ambulance posts:*

1. *Pack;* 2. SEATS.

Nos. 1 and 3 raise the curtain, if necessary, and open the tail-gate; Nos. 2 and 3 enter the ambulance and face the front and rear seats of their respective sides; each man releases the legs and secures them against the seats, then, seizing the front of the seat with both hands, lowers it to the side of the ambulance, and then makes in like manner the opposite seats. No. 2 then unfastens the strap which holds the litter-supporting post to the roof of the ambulance, swings the post to a vertical position, and places it firmly in its socket. Nos. 3 and 2 now resume their positions *at ambulance posts.*

Seats can be prepared or packed on one side only, leaving room on the packed side for two recumbent patients by the commands:

Prepare (or *pack*) *seats, right* (or *left*).

The litter being *lifted* at the commands:

1. *Take post to load ambulance;* 2. MARCH.

the squad proceed to the ambulance. No. 4, starting ahead in double time, lays the arms and accoutrements of the patient (which he carries) on the ground by the right rear wheel; he then raises the curtain, if necessary, opens the tail-gate, observes the condition of the ambulance, and (resuming his post at the litter) reports it to the squad leader. Upon approaching the ambulance the litter is wheeled about so that the head of the patient is toward the rear of the ambulance and two paces from it, when the litter is halted and lowered. If it be necessary to prepare the ambulance before loading, the squad takes posts at ambulance, No. 4 remaining in charge of the patient; if ready for the reception of the lower litter (or berth) the commands are given:

1. *Prepare to load;* 2. LOAD.

(*a*) At the first command No. 2 faces about, No. 3 steps around his left handle and takes post at the patient's left shoulder; No. 1 takes post opposite No. 3; all facing the litter stoop, No. 2 grasping his handles, and Nos. 1 and 3 their respective poles; No. 4 watches the patient and otherwise renders any needful assistance. At *load*, the bearers slowly raise the litter to the level of the floor of the ambulance and advance to it, being careful to keep the litter in a horizontal position; the legs are placed on the floor by Nos. 1 and 3, and the litter pushed in by No. 2, assisted by the others. When this is accomplished, Nos. 1, 2, and 3 are in position *at ambulance posts.* No. 4 places the arms and accoutrements of the patient (if any) under the litter, and then takes his position on the right; Nos. 1 and 3 close the tail gate and, if necessary, lower the curtain. The squad may then be faced to the left or about and marched in any desired direction.

(*b*) 1. *For upper berth, prepare to load;* 2. LOAD.

At the first command the bearers face about and Nos. 2 and 3 stoop and grasp their respective handles.

At *load* the litter is lifted and advanced to the rear of the ambulance, when Nos. 1 and 4 face the litter and grasp their respective poles opposite the patient's shoulders; No. 3 relinquishes hold of the front handles, mounts the step (see Fig. 4762, loading upper berth, No. 1) and enters, when he resumes hold of the handles, as in passing obstacles. The litter is raised and passed into the ambulance, care being taken to keep the litter in a horizontal position (see Fig. 4763, loading upper berth, No. 2); No. 3, inside at the front, and No. 2 on the rear step, place the left (or right) handles in the receiving sockets and slip the straps over the right (or left) han-

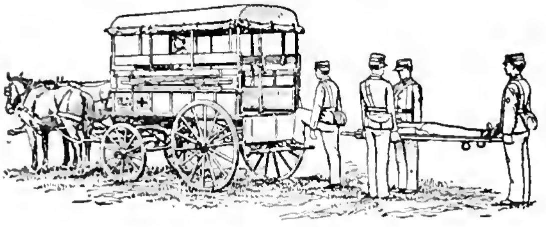


FIG. 4762.—Loading Upper Berth, No. 1

dles. Nos. 1 and 4 assist in loading by supporting the litter on their respective sides until the handles have been secured; No. 3 steps over the front seat, jumps to the ground, and the squad takes position at ambulance posts. No. 4 places the arms and accoutrements of the patient, if any, in the hammock, and then takes his position on the right; Nos. 1 and 3 close the tail-gate and, if necessary, lower the curtain. The squad may then be faced to the left or about and marched in any desired direction.

(*a*) The squad being *at ambulance posts:*

1. *For lower berth prepare to unload;* 2. UNLOAD.

At the first command, Nos. 1 and 3 raise the curtain, if necessary, open the tail-gate, and No. 2 takes hold of

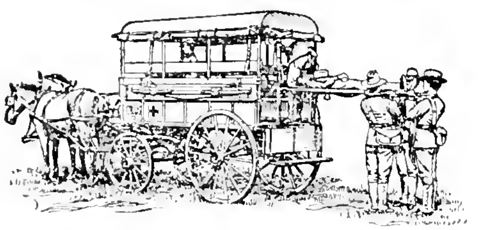

FIG. 4763.—Loading Upper Berth, No. 2.

the protecting handles of the litter; at unload, No. 2 draws out the litter, assisted by Nos. 1 and 3, who, facing inward, support the poles until the inner handles are reached. The litter, carefully supported in a horizontal position, is then lowered with the head of the patient two paces in rear of wagon; No. 4 closes the tail-gate, and all take posts at the litter.

(*b*) The squad being *at ambulance posts:*

1. *For upper berth, prepare to unload;* 2. UNLOAD.

At the first command Nos. 1 and 3 raise the curtain, if necessary, and open the tail-gate; No. 3 runs to the front of the ambulance, climbs in, stepping over the front seat, and faces the rear, grasping the front handles. No. 2 mounts the step and grasps the rear handles. Nos. 1 and 4 face the litter (see Fig. 4764, unloading upper berth). *At unload,* the handles are lifted and freed from their fastenings by Nos. 2 and 3; the litter is carried out, Nos. 1 and 4 on their respective sides supporting the litter, first at the foot and then at the head, as Nos. 2 and 3 step down from the ambulance. The litter, carefully supported in a horizontal position, is then lowered, with the head of the patient two paces in rear of the wagon; No. 4 closes the tail-gate and all take posts at litter.

(*a*) To load lower berth with two bearers, the litter being lowered in position for loading, at *prepare to load,* the bearers take posts on their respective sides, mid-length of the litter and facing it; they stoop and grasp each pole firmly with both hands. *At load,* they lift the litter and push it into the ambulance.

At *unload,* each bearer grasping his handle, they partly withdraw the litter, then shifting their hands to their respective poles and facing each other, they continue to withdraw it until the head reaches the rear of the ambulance, when they lift the litter out and lower it to the ground.

(*b*) To load the upper berth with two bearers, the lower berth is first loaded, as here described, and the litter is then lifted to its position and secured, one bearer inside the ambulance at the front handles and the other on the step at the rear handles. To unload, this movement is reversed.

The right side of the ambulance is always loaded or unloaded first, unless otherwise ordered. With more than one recumbent patient, the upper berth should be the first to be loaded and the last to be unloaded. The lower berth is the last to be loaded and the first to be unloaded.

When necessary to load the feet first at the commands: *By the feet, take post to load ambulance, march,* the litter is lowered with foot toward the ambulance, when the loading proceeds as above described, excepting that No. 3 remains between his handles, No. 2 takes post opposite the right ankle, and No. 4 opposite him.

At the conclusion of the drill with ambulances the detachment is reformed in line.

Two-wheeled ambulances designed to be drawn by a single animal have met with favor in nearly all the European armies, and during the Civil War were supplied to the United States troops. They are usually made to accommodate two recumbent or four sitting-up cases. Their principal advantages lie in their lightness and ability to cover ground which is impracticable for a four-wheel vehicle. They proved to be unsatisfactory in our Civil War, and were generally unfavorably reported upon by the medical officers who had had experience with them. They were found to be uncomfortable to their occupants on account of the jolting, and, being of light construction, were easily broken. The reason they have met with more favor in Europe than in the United States is no doubt due to the fact that our roadways are generally inferior to those of Europe. There can be little economy in their employment, as their carrying capacity is less than half that of our present service ambulance. Theoretically, a light two-wheeled vehicle should be admirably adapted to the removal of the wounded from the battlefield; but practically this can be done more expeditiously and with greater comfort to the wounded and safety to the injured and their bearers by hand-litters. The British in the South African War made use of the Indian "tonga," a light two-wheeled vehicle drawn by two ponies, for the transportation of wounded: it accommodates two recumbent patients. It is reported as having given satisfaction, and is described as being "so well arranged and padded that the occupants are seldom hurt by striking against the sides with rough jolting, unless quite helpless."

In cities the motor ambulance has almost entirely superseded the horse ambulance in the transportation of the disabled. However satisfactory this vehicle has proved to be for urban use and in regions where good

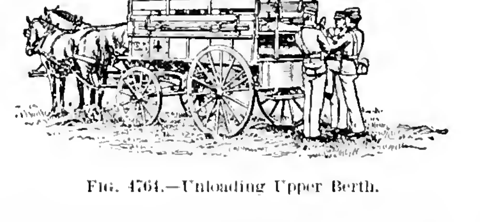

FIG. 4764.—Unloading Upper Berth.

roads exist—and its superiority under such conditions is unquestioned—it is doubtful whether it can ever entirely replace the present service ambulance in the transportation of the sick and wounded of the military service. A military ambulance must be able to go over any ground practicable for wheeled vehicles—over steep grades, through mud, sand, and ruts. Its construction must be simple, so that it can be managed by the average enlisted man, and when disabled must be capable of being readily repaired with the materials at hand and by the men who accompany it. The motor wagon does not as yet fulfil these requirements. About the base and at times perhaps along the lines of communication a motor ambulance would prove a satisfactory substitute for the present service wagon; but only exceptionally could it accompany the field hospitals or reach the ambulance stations. In several of the European armies motor vehicles are used for hauling wagon trains and transporting staff officers, couriers, and supplies, and recent trials have demonstrated that, within certain limits, this means of transportation is feasible for military purpose. Perhaps the future will develop a motor ambulance which can be used under all military conditions. The advantages of such a vehicle would not be inconsiderable; there would primarily be a great saving in the transportation of animals and forage; the fuel, if it be a fuel motor, would probably be of small bulk; and the increased speed of such a vehicle would extend its operations and increase its carrying capacity. So far as known to the writer, a motor ambulance which fulfils all the requirements of the military service has not yet been produced.

Circumstances must often arise when ambulances are not available for the transportation of the disabled, and after an important engagement with excessive casualties the number of ambulances, even with a most liberal allowance, will hardly ever be sufficient in number to remove promptly all the wounded; so, too, in the service of evacuation from the field into base and general hospitals, rarely will it happen that additional transport will not be required. Recourse under such conditions must then be had to other means. If railroad trains are impracticable, there will usually be army wagons, and the wagons and carts of the country; at times artillery caissons, though poorly adapted to this purpose, have been so employed. Where cots or litters are at hand, they should be used for the recumbent patients; the army wagon, with cover, which can carry two recumbent patients on litters or cots, or three recumbent without litters, or eight sitting-up cases, has often proven a satisfactory substitute for the ambulance.

When litters or cots are not available, the bottom of the wagon should be covered with a bed of hay, straw, leaves, or other material. Wagons with springs, for obvious reasons, are always to be preferred. Elastic rods of wood, properly covered with canvas and hay, laid across a wagon box, make a very good springy bed, or such a bed may be made by interlacing straps or ropes across a wagon body. Hay wagons with a thick layer of hay in the bottom make fairly comfortable conveyances for the disabled. Sleighs and sleds suggest themselves as excellent means for the transportation of the sick and wounded; the advantages of their employment under favorable conditions are so evident that further remarks regarding them are unnecessary.

In the service of evacuation, by which is understood the transportation of the sick and wounded from the field or division hospitals to the more permanent hospitals at the base and beyond, the means of transportation already mentioned will usually be inadequate, even if these means were available for such service. General and base hospitals are usually located with a view to their accessibility of communication with the operating force; if roads do not already exist, they are constructed as the troops move on. So, too, if the exigencies of the campaign require railroads or lines of steamboats, these will be constructed or established. Thus the means of transportation that carry forward troops and supplies to the front may be utilized in bringing back the disabled. The service of evacuation is of importance, as by it the field hospitals are emptied, enabling them to move promptly and expeditiously with their respective commands, holds them ready for the reception of the sick and wounded from subsequent military operations, and removes centres of disease from the active army. Besides, at the more permanent hospitals the sick and wounded can be better cared for than would be practicable in a moving hospital.

In some of the European armies hospital trains, made up of cars especially constructed and equipped for carrying sick and wounded, are maintained as part of the transportation of the army. In such trains the hospital cars are fitted up as wards, the beds being either fixed berths or litters are used as berths, upon which patients may be carried to and from the cars. The regular hospital car of the German hospital train has twelve beds with hair mattresses, bedside tables, two reclining chairs, hammocks for clothing, lavatories and lockers. The beds can be lifted off and used as litters, and are arranged on a system of springs, allowing universal motion. A kitchen car is attached to each train, and is equipped with ranges, refrigerators, cooking utensils, and crockery, etc., sufficient for three hundred sick. A freight car is also attached, for carrying baggage and stores. Hospital trains are more often improvised from such rolling stock as may be available, and for this purpose sleeping-cars, passenger coaches, baggage and freight cars may be used.

During the War of the Rebellion in the United States many thousand wounded were transferred from the front to general hospitals by rail; after the battle of Chancellorsville, for instance, 9,000 men were moved from the army in three days; and after the battle of Gettysburg 15,425 wounded were moved in fifteen days. In several cases more than a thousand patients were reported as having been carried upon a single train. It is manifestly impracticable to have at hand sufficient regularly fitted and equipped hospital cars to transport such large numbers of disabled men, and in the instances above cited the trains were composed almost entirely of freight cars, both box and open cars; the floors of the cars were covered with a thick bed of hay, grass, straw, or leaves, upon which the patients were laid; the open cars were covered with an improvised roof of canvas.

Ordinary passenger coaches are also used for carrying sick and wounded; in some cases the seats are removed and the patients laid upon the floor, either upon litters, or upon bedsacks, or loose hay or straw. Where the seats are not removed, berths may be made by laying boards across from seat to seat or over the backs of the seats. During the war just referred to our hospital trains were usually composed of freight cars and passenger coaches, which had been converted into hospital cars by placing two rows of stout stanchions on each side of the car at distances corresponding to the length and breadth of the litter. From pins or hooks fastened to the stanchions the litters were suspended in two or three tiers, depending on the height of the car. In some cases india-rubber rings were employed for suspending the litters, on the theory that the elastic action of the rings would minimize the vibration and jolting; experience demonstrated, however, that if the rings were thin enough to permit their elasticity to come into play the jolting was increased; while, on the other hand, if the rings were thick and strong, there was no elastic action, and any other method of suspension acted as well. In another plan, fixed berths were constructed in the cars by means of boards and stanchions arranged as described above. Upon these the patients were placed either upon the litters which brought them to the train, or upon mattresses or bedsacks filled with straw. In the recent Boer War in South Africa the British converted freight cars into hospital cars by this method; the berths were arranged in two tiers (Fig. 4765). Makin says of these cars that they "seemed to offer little scope for improvement except in minor details. To them much of the success in the treatment of the wounded, who had to traverse the immense distances incident to South Africa, must be attributed." A train of hospital cars fitted up in England and sent to South Africa, in which the berths were arranged in three tiers, was reported upon as having been less satisfactory.

In the German army the regular hospital trains are supplemented, when the necessity therefor arises, by improvised trains composed of freight cars. For this purpose "knock-down" lockers for carrying the required equipment, and springs which reach across the bottom of the car, each of which will support four litters, are held in readiness.

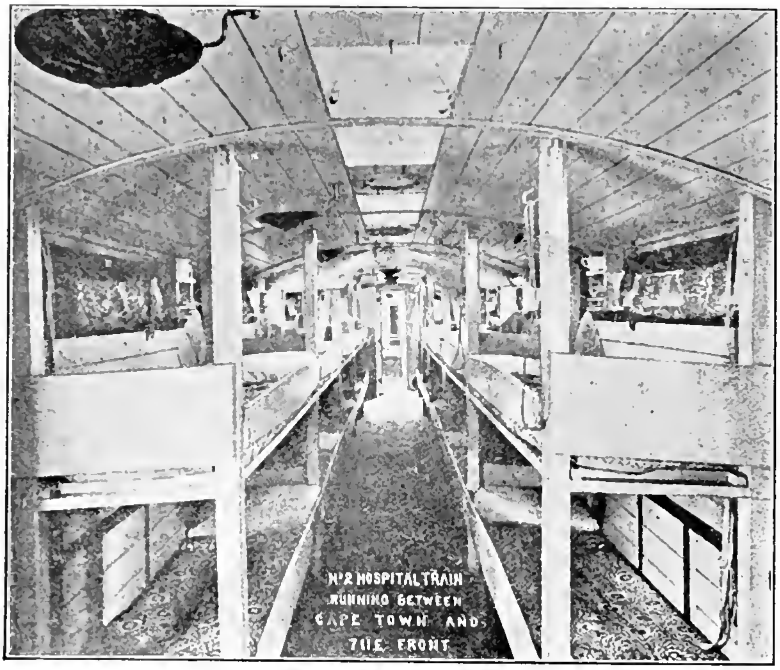

FIG. 4765.—Interior of British Hospital Car. (After Makin.) (Boer War in South Africa.)

In another arrangement litters are suspended from supports by means of chain slings with spiral springs.

In the English, French, and Norwegian services freight cars are converted into hospital cars by a system in which the litters are supported in two tiers in hinged frames, suspended from ropes running across the top of the cars. In this system, which is known as Zavodovski's (Fig. 4766), the frames in which the litters rest are not rigidly fixed, thus permitting a slight swaying motion, which to a certain extent relieves the vibration and jolting.

During the Spanish-American War a regularly equipped hospital train was in operation transporting sick and wounded from the different division hospitals to the general hospitals. This train was composed of ten hospital cars, a kitchen and dining car, a combination car, and a so-called "private" car, which latter was used as quarters for the officers of the train. The hospital cars were of the type known as Pullman "tourist" sleeping-cars, chartered from the Pullman Company. In these cars the seats, which are arranged in pairs facing each other, may be converted into beds; above these seats is a tier of beds, secured by hinges to the side of the car; when not in use these beds are swung up to the roof and locked there by suitable fastenings. The space under the seat is enclosed, forming a box in which the bedding is kept when not in use; the upper berth, when closed, contains its bedding likewise. Each car has lockers for bed linen and clothing, fixed wash basins, water tanks, and closets. In this train each berth was supplied with mattress, sheets, pillow, and pillow case, and a pair of blankets, and each car was provided with the usual appliances needed in a hospital ward, such as bed pans, urinals, basins, etc. The cars were without carpets or curtains, for obvious reasons; the seats were of woven cane, a point of some moment where sick and wounded are to be carried. Some of the cars had twenty-four berths, others twenty-eight, making the capacity of the train about two hundred and forty. If only convalescents were to be carried and the journey was of short duration, the train could accommodate double that number without crowding. The dining and kitchen car was of the pattern used in the passenger service of our railroads. It contained a compact and complete kitchen, with range, refrigerators, cooking utensils, and appliances sufficient for the full carrying capacity of the train. In this kitchen were prepared all meals for patients, including special diets, as well as those for the entire personnel of the train. The combination car contained a baggage and a passenger compartment; the baggage compartment was the train storeroom, in which were carried patients' effects, stores, tools, bedding, tents, litters, etc.; the passenger compartment, from which most of the fixed seats had been removed, was used as the train office, dispensary, and operating room, and was equipped with desk, medical and surgical chests, and a folding operating table.

In loading the train with patients it was "broken" after every second car, sufficient space being allowed between the cars to permit of easy handling of the litter; this was passed upon the platform by two bearers, one end reaching through the doorway; from here it was taken by another squad of two men who carried it into the car, and with the assistance of a third bearer transferred the patient to the bed. Patients requiring special attention or who were helpless were placed in lower berths, where they could be more conveniently attended. Upon the arrival of the train at its

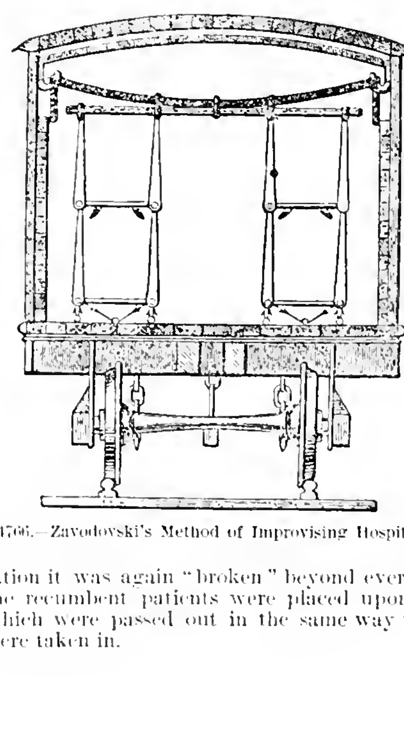

FIG. 4766.—Zavodovski's Method of Improvising Hospital Cars.

destination it was again "broken" beyond every second car; the recumbent patients were placed upon the litters, which were passed out in the same way in which they were taken in.

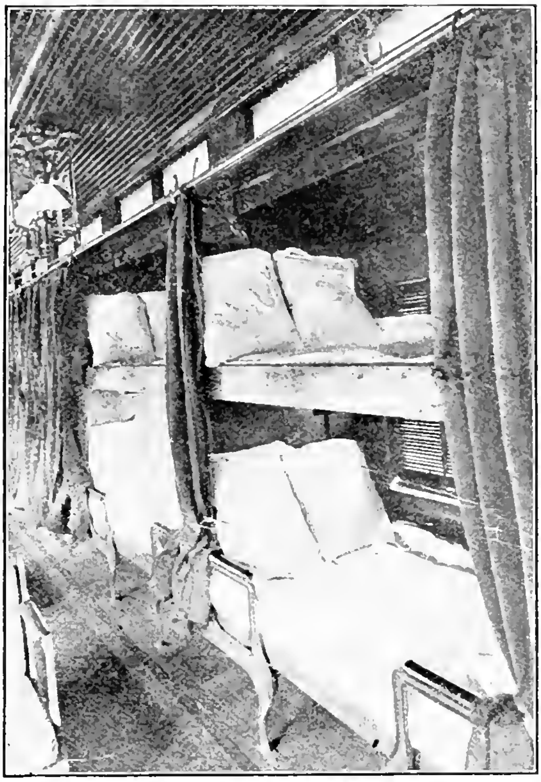

FIG. 4767.—Interior of Tourist Sleeping-Car, with Beds Prepared. Used during Spanish-American War, 1898. (This illustration should be without curtains or carpet.)

Stress has been laid by military surgeons upon the advantage of transporting patients (especially wounded) on trains upon the litters which bring them; this advantage is more fancied than real, as with trained men patients, even though severely wounded, can be safely and comfortably transferred from litters to beds and from beds to litters.

In the instances where the receiving hospitals were situated at a distance from the railroad track, electric street cars were used to transfer patients from the train to the hospital. In these, recumbent patients were placed upon mattresses laid upon the seats and upon litters resting on the floor. When the hospital was near the railroad track, patients were transferred to it by hand-litters or ambulances.

This train was not merely a railroad ambulance, but a moving hospital, organized and equipped to treat sick and wounded as well as transport them. Its personnel was quartered and subsisted upon it during the entire period that it was in operation, and the usual hospital routine and discipline were observed. It made many journeys of more than a thousand miles in length and of two days' duration. Patients were examined and prescribed for on admission, and their diagnoses were recorded; while en route regular morning and evening visits were made, and the more seriously ill were visited as often as was deemed necessary; wounds were dressed and minor operations performed. Cases of all kinds, except contagious diseases, were carried, and it is worthy of note here that they generally bore the journey well in spite of the heat and dust which prevailed during the summer months. Even typhoid fever cases in the first week and during early convalescence were not unfavorably affected, though those in the height of the disease, as might have been expected, did poorly.

Cars of the type constituting this train are heavy in weight and construction, and are mounted upon six- or eight-wheel trucks; they are supported upon the trucks by an efficient system of springs; these factors tend to lessen the vibration and jarring incident to all railroad travel, a matter of consideration where sick and wounded are to be carried. Such cars have ample window space, are readily ventilated, and easy to keep clean; the aisle running through the car lengthwise from door to door between the beds permits of convenient and expeditious loading and unloading of the litter cases, while the facility with which the seats can be converted into beds and *vice versa*, enabling patients to sit up or lie down as the necessity of their cases might require, is a valuable feature possessed by no other improvised hospital car. Fig. 4767 shows the interior of such a car with beds prepared; Fig. 4768, with seats prepared.

Undoubtedly the best type of railroad car for the improvised transport of sick and wounded over long distances—in the United States at least—is the Pullman tourist sleeping-car, or a car similar to it in construction and arrangement.

Hospital trains composed of cars especially devised and constructed for the transportation of the sick and wounded of the military service would possess many valuable features, which are either impracticable or impossible in any improvised arrangement, and would be most desirable adjuncts to an army. Few governments, however, find it expedient or necessary to maintain such trains on hand ready for use; consequently such means as are available or can be speedily made so will have to be employed. For short hauls and in sudden emergencies almost any kind of rolling stock can be used, and will prove satisfactory. Baggage, freight, and ordinary

FIG. 4768.—Interior of Tourist Sleeping-Car, with Seats Prepared. Used during Spanish-American War, 1898.

passenger cars are usually at hand, as they will have brought troops and supplies to the front, and under these conditions may be used without making any changes in them. But for systematic work, as in the service of evacuation, and where sick and wounded are to be transferred over distances requiring more than three or four hours of travel, better arrangements should be provided. Under such circumstances, in the absence of specially devised and equipped hospital cars, sleeping-cars of the type described above are desirable. When these cannot be secured, such cars as may be available must be so arranged as to permit the transportation of the sick and wounded with the least discomfort. Fixed berths or supports for litters must be erected; a water-supply, water-closets, lockers for linen, seats for attendants and for patients who are able to sit up, should be provided. If box cars are converted into hospital cars, special provisions must be made for heating, lighting, and ventilation. One car will be fitted up as a kitchen and dining car, with range, cooking utensils, refrigerators, dishes, tableware, etc., sufficient for the full carrying capacity of the train. Another car will be arranged as office and dispensary and storeroom, with desk, medicines, medical and surgical chests, and medical stores.

The necessary personnel of a hospital train will depend upon the capacity of the train, the character of the patients carried, and the length of the journey.

The Manual for the Medical Department of the United States Army, edition of 1902, gives as the personnel required for a hospital train of nine cars, seven of which are used for patients with a capacity for two hundred men, the following:

Two Medical Officers.—One captain, assistant surgeon, commanding. One lieutenant, assistant surgeon.

Three Non-Commissioned Officers of the Hospital Corps.—One sergeant, first-class. Two sergeants.

Twenty-four Privates of the Hospital Corps.—Twenty nurses. Two cooks. Two medical officers' orderlies.

The number of non-commissioned officers here prescribed will prove adequate, but the medical officers and privates are not sufficient in number. One medical officer will usually be detailed as quartermaster and commissary of the train, and would only occasionally be free to attend patients, leaving but one other officer to look after the professional needs of two hundred patients and attend to the numerous other duties incident to a service of this character; three medical officers would be more satisfactory. If the journey to be performed be twenty-four hours or more in duration, and if it be assumed that each hospital car carries at least twenty-four patients, three nurses will be needed to each car—two for duty during the day and one for night duty; two additional men would also be required for work in the dining car. There is no economy apparent in limiting the number of cars for patients to seven; ten cars could be as easily hauled and administered; this would increase the capacity of the train by one-third, and would only necessitate an increase of three nurses to each car.

The problem of the transportation of the disabled in the military service is one which confronts the military surgeon under varying conditions and circumstances, and is no less a question of importance to the military commander. In many wars lives have been lost which might have been saved had adequate means of transportation been at hand. Even at the present day the means at our disposal are often crude and still limited; advance has been made, more yet remains to be done. War can never be waged with comfort to its participants. Nevertheless it behooves us as military surgeons to mitigate its horror and suffering as best we may. Improvements in both means and methods of transportation for the disabled will contribute to this end. *Charles Richard.*

TRANSPOSITION OF THE VISCERA.—(Synonym: Situs Viscerum Inversus.) DEFINITION.—In this condition the relations of the various organs of the body are exactly reversed: right and left are changed about like the reflection in a mirror. As applied to the heart, this organ is on the right side of the chest, with the apex directed outward, giving the anomaly known as dextrocardia. The lungs may take part in the transposition, the left having three lobes and the right two. The position of the aorta and its branches may be reversed. The spleen is located in the right hypochondrium and the liver in the left. The stomach may also be affected in this change, the fundus lying to the right of the median line and the pylorus to the left. The sigmoid may lie on the right side of the abdomen and the cæcum and appendix vermiformis on the left. Transposition of the viscera may be *total* or *partial*. The heart alone may be transposed; or the transposition may be limited to one or more of the abdominal organs. Complete transposition is much more common than partial. The congenital transposition, which is under consideration in this article, must be carefully distinguished from acquired displacements of organs, such as the dextrocardia due to traction or pressure from disease in the thoracic cavity.

HISTORY.—Gruber made a remarkable collection of all cases found in literature up to the year 1865. Of the 79

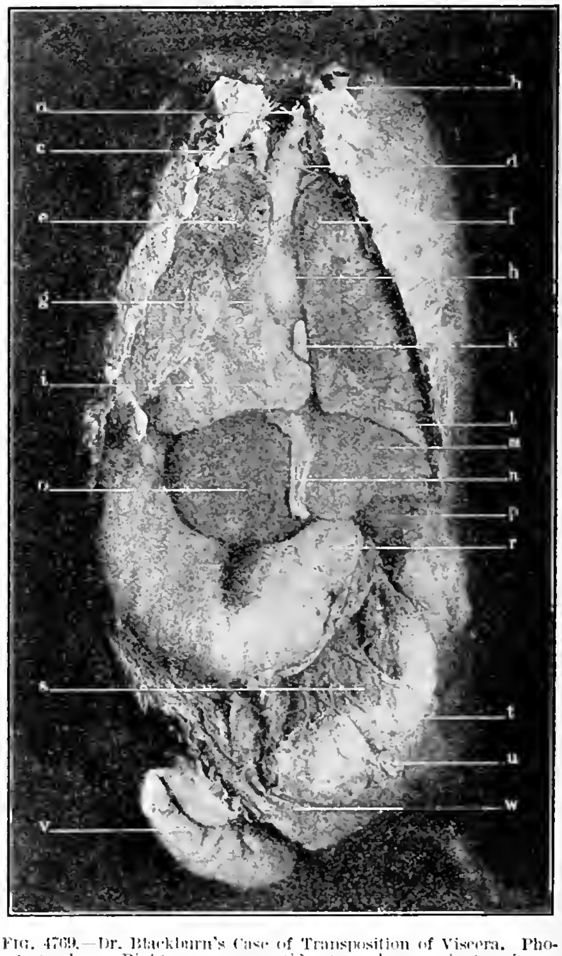

FIG. 4769.—Dr. Blackburn's Case of Transposition of Viscera. cases which he reports, only 5 or 6 were discovered during life. This fact seems rather remarkable since his report covers a period of more than two centuries. In 1643

Petrus Servius reported the first case as occurring at Rome.

Küchenmeister, up to the year 1888, collected 149 cases. The majority of these were discovered in the anatomical

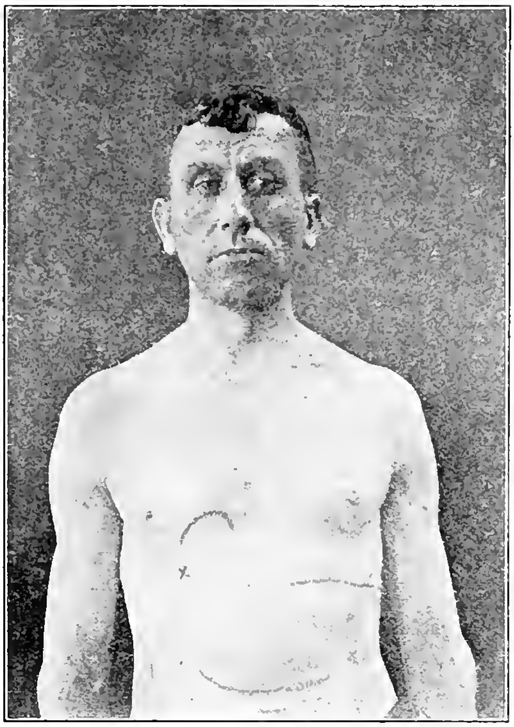

FIG. 4770.—Photograph of Schüppel's Case of Transposition of the Viscera. The X below right nipple indicates the position of the apex beat. The curved line above shows the absolute heart dulness. The straight line below the left nipple indicates the upper border of the liver dulness. The X below this line indicates the lower border of the liver dulness. The curved line above the navel indicates the greater curvature of the stomach. The curved line low down on the right side indicates the splenic dulness.

laboratory and on the post-mortem table. Pic in 1895 increased the number of reported cases to 190. Lochte up to the year 1894 collected 13 cases of partial transposition of the viscera. In more than half of these very poor descriptions were given.

An attempt to collect all the cases of situs viscerum inversus is extremely difficult and unsatisfactory, because they are reported in the literature under numerous headings. Perhaps something like 300 of these cases have been reported.

Until recent years cases of transposition of the viscera have been discovered, studied, and reported chiefly by anatomists and pathologists. Judging from my own personal experience with these cases, and from that of a large number of prominent clinicians and anatomists to whom I addressed letters of inquiry regarding their experience with transposition of the viscera, it would seem that the pendulum has swung about of late years, and that now a much larger percentage of cases of transposition is discovered by the clinician. This fact is a natural result of the much more frequent and careful physical examinations that are now being made. However, even with this improvement, all physicians know that a very small percentage of even sick people submit to careful physical examination, and that the percentage of the entire population who are thus examined is extremely small.

Since the spring of 1897 I have seen in hospital and private practice six cases of transposition of the viscera. It is rather a remarkable fact that three of these cases were seen within the short period of six months. I am also personally familiar with three other cases of situs inversus, discovered in the living subject by members of the internal medical staff of the University of Michigan, two by Dr. Warthin, and one by Dr. Cowie.

These cases have been reported in detail in the *American Journal of the Medical Sciences*, November, 1902, and in the *Vaughan Festschrift*, 1903.

In reply to my letters the following facts were gleaned: Five well-known internists and four professors of anatomy had never seen a case of transposition of the viscera. In the remaining letters 37 cases were reported. All save 6 of these were discovered during life. In this country, at least, cases of transposition are nowadays much more frequently discovered during life than after death. Note the contrast between Gruber's report and my own. Of his 79 cases only 5 or 6 were discovered during life. In my collection, which simply covers the cases reported in the letters referred to, together with those with which I am personally familiar, are 46 cases, of which 40 were discovered during life.

Method of Examination.—Careful inspection, palpation, percussion, and auscultation of the chest are of course prime essentials. The failure to find the heart apex and heart dulness on the left side most often puts one on the right track. A careful examination of the right chest may then reveal a dextrocardia. This is at once a key to the physical condition. An absence of liver dulness is then detected in the right hypochondrium. It is sought for and discovered in the left hypochondrium; the splenic dulness will then be found in the right midaxillary line.

The position and outline of the stomach may be demonstrated by inflation or by the use of the gastrodiaphane; the same is true of the sigmoid. x-Ray examination of the heart with the fluoroscope easily demonstrates the right-sided position of this organ. (See Fig. 4771.)

Theories Explaining the Development of Transposition.—These are chiefly of interest to the embryologist and anatomist, and will hardly be understood except by those who have devoted special study to embryology. The following are some of them.

Von Baer explains transposition by the turning of the embryo in the opposite direction; that is, the embryo normally lies on the left side of the umbilical vesicle; but if it lies on the right side, then we have transposition. According to him this occurs at the beginning of the developmental period.

Förster considers situs inversus a malformation in which the transposition of the anlagen takes place in the

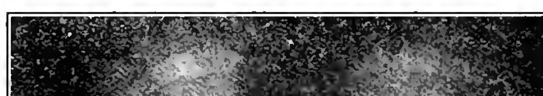

FIG. 4771.—Radiograph showing Transposition of the Heart to the Right Side. (Schüppel's case.)

first embryonal formation. In the double monster the fœtus of the right side shows a complete transposition, while the fœtus on the left side shows a normal situs.

Rindfleisch believes that a spiral turning of the blood column is responsible for the displacement of the heart. Normally it flows from left to right, but in situs inversus an opposite direction must obtain. The asymmetry of the heart is made responsible for all asymmetry in the animal body.

Virchow emphasizes the influence of the umbilical cord. In situs inversus it is wound spirally to the right; in situs solitus to the left.

Küchenmeister thinks that the location of the fertilized germinal disc at the surface of the egg is the essential thing. The normal situs in single birth probably depends upon growth of the germ from below upward, instead of from above downward. He says that from this it must be self-evident that the turning of the embryo has been inverted. This must also affect the later spleen side and the side of the arterial heart. Concerning the congenital partial situs viscerum, solito inversus, which shows itself either in the chest or in the belly, but not in both places at the same time, he believes that the growth on the whole follows the type for the situs inversus. The rarer partial situs is an inhibition formation which grows according to the type of the normally projected embryo.

Martinotti in the situs transversus of the single born emphasizes the condition of the vena omphalo-mesenterica, first mentioned by Dareste. The direction which the heart loop takes depends upon the dissimilar growth of the two halves of the vascular area. Under normal conditions a dissimilar formation of the two halves exists. The left omphalo-mesenteric vein is more developed than the right; the right gradually disappears. The heart reacts in a very sensitive way toward the cause of situs transversus.

Marchand says that the loop formation of the vena omphalo-mesenterica about the intestines under normal conditions prevents the intestines from slipping toward the right. So a right turning takes place if the loop formation is absent. He considers a left-sided persistent vena omphalo-mesenterica the cause of the right position of the stomach. In a more recent monograph Marchand states it as his belief that the development of the vena omphalo-mesenterica can have no influence upon the rotation of the stomach.

Lochte advances the view that the growth of the organ considered in the sense of situs solitus is associated with a persistence of left-sided omphalo-mesenterica and umbilical veins, while those of situs transversus totalis, on the other hand, are associated with corresponding right-sided veins.

To the clinician transposition of the viscera presents many interesting problems in differential diagnosis. The displacement of the heart to the right makes it necessary to examine the lungs and pleura carefully, in order to exclude acquired displacement. The discovery of an enlarged area of dulness in the left hypochondrium suggests a number of possibilities. It is most likely an enlarged spleen—either of leukaemia, malaria, splenomegaly, or some other disease. This point is illustrated by actual cases in practice. In Munson's case the diagnosis of an enormously enlarged spleen had been made; and the displacement of the heart was thought to be due to dilatation.

In the normal patient it is a very common experience to find an entire absence of liver dulness in the right hypochondrium. It is also common to find that the apex beat is neither seen nor felt on the left side, especially if the patient is quiet and in the horizontal position. Heart dulness is also frequently absent. So it is easy to understand how these cases of transposition often are overlooked.

It is possible to mistake an aneurism of the arch for a dislocated heart. This fact was recently brought to my attention.

Gruber refers to the following errors in diagnosis. In one case of transposition a pain in the right hypochondrium led to the diagnosis of a chronic inflammation of the liver. In another case a soldier was wounded in a duel, in the right hypochondrium; from the position of the wound and the vomiting of green fluid it was thought that the liver had been penetrated. In a third case, in the Würzburg clinic, the transposed liver was diagnosed as a spleen tumor. In a fourth case, one of cancer of the pylorus, in a transposed stomach, the hard tumor felt deep in the left hypochondrium was thought to belong to the left part of the stomach or the pancreas.

In appendicitis developing in a patient with transposition of the viscera the signs and symptoms would of course be located on the left side instead of on the right side. The surgeon would choose Monroe's point instead of McBurney's point for the site of his incision.

Gruber arrived at a number of interesting conclusions from a study of 79 cases. "Concerning the sex there were 49 men, 19 women, and 11 in which sex was not mentioned. These individuals lived as long as those with normally placed organs. Five of the 19 women lived to an age between seventy and eighty-four.

The women were normally fruitful. One gave birth to twelve children. Among the 79, 4 died an unnatural death, and only 4 were extremely malformed. There was transposition of *both* chest and abdominal organs in 71; of the abdominal organs alone in 8. In the first kind the transposition was complete, in the latter incomplete.

The lungs were transposed in 35 of 71 cases; the right had two lobes, and the left three. In 2 cases they were not transposed; in 2 both lungs had two lobes; in *one* the right had one lobe, and the left two lobes.

Curvature of the dorsal portion of the spine is mentioned in only 11 cases. In 7 of these it was to the left, in 4 to the right as normally.

We cannot draw the conclusion that persons with transposition are more likely to be left-handed than those with normally located viscera.

The position of the testicle was mentioned only 7 times. In 4 the right was lower, in 1 the left. In 1 the left had not descended.

The lower position of the right testicle is unimportant as a sign of situs inversus.

In only 9 cases were there notes on the position of the kidneys. In 7 the left was lower, in 2 the right.

In 32 cases in which the vessels arising from the arch of the aorta are mentioned, these were transposed 29 to 30 times.

H. Steinhauser mentions the fact that in the operation of œsophagotomy, it is well to know that the œsophagus lies over the right trachea in persons with transposition.

In situs partialis the transposition of the abdominal organs may be very irregular. In one case the stomach and duodenum were normally located, while the other organs were transposed. In another case the liver alone was transposed.

In 1888 a case of pure dextrocardia with congenital pulmonary stenosis, without malposition of the viscera in general, was shown to the Vienna Medical Society by Dr. Gruss. In discussing the case, von Bamberger concurred in the diagnosis, and remarked that Professor Schrötter had lately stated that no single case of pure dextrocardia had ever been proved, whereas all anatomists of experience, for example Rokitansky, Friedberg, Förster, *et al.*, had mentioned such cases, and he himself had seen two.

The above quotation emphasizes the fact that partial situs is a much rarer condition than complete. If the transposition is located in the abdominal cavity, it will most likely be overlooked in the physical examination.

James Rae Arneill.

TRAUMATOL—iodocresol, orthocresol iodide, $C_6H_3.CH_3.OI$—is a reddish, odorless, insoluble powder which is used as an antiseptic substitute for iodoform in wounds and ulcers. It is an efficient drying powder and deodorizer. *W. A. Bastedo.*

TREMATODA.*—The class Trematoda, or Flukes, constitutes one of the prominent subdivisions of the

* A general discussion of parasitism and its effects is to be found under the heading *Parasites*.

branch or phylum Plathelminthes, the characteristics of which were outlined under the Cestoda. The group was recognized as distinct in 1800 by J. G. H. Zeder, a practising physician in Germany, who with great clearness of vision separated the then accepted class of Helminthes or intestinal worms into five groups of closely related forms. These groups received in 1809 at the hands of K. A. Rudolphi, the celebrated Berlin helminthologist, the scientific names of Nematoda, Acanthocephala, Trematoda, Cestoda, and Cystica. The latter have since been shown to be immature stages of the Cestoda, and C. Vogt in 1851 demonstrated the unnatural character of the association Helminthes, making as a natural group the flatworms in which are now included the flukes, the tapeworms, and the free living flatworms, as three great classes of the phylum designated Plathelminthes.

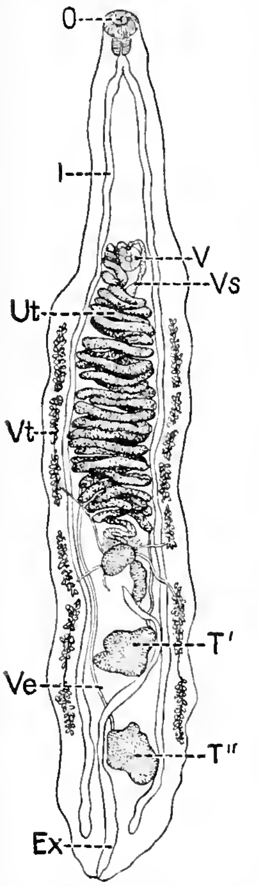

FIG. 4772.—*Opisthorchis pseudofelineus* Ward. From liver of cat. *Ex*, Excretory bladder; *I*, intestinal crura; *O*, oral sucker; *T'*,*T''*, testes; *Ut*, uterus; *V*, ventral sucker; *Vt*, vitellaria; *Ve*, vas efferens; *Vs*, vesicula seminalis. × 7. (Original.)

In certain features, such as the simple body, the presence of an alimentary canal, and in some cases even of special sense organs, the Trematoda stand much nearer the free living forms than do the Cestoda, although all of the species included in both classes are parasitic. The consistent parasitic habit, in which the flukes resemble the tapeworms, is varied by a modification in degree among the flukes which serves to show their relation also to free living species and contrasts strongly with the intensive endoparasitism of the Cestoda. Thus among the flukes there are not only the endoparasitic species, but also such as are ectoparasitic and preserve in some degree those features of free living forms that are lost with the assumption of endoparasitic existence. Withal the group is a well-defined one, and manifests greater uniformity in structure than the Cestoda, while it also embraces both fewer species and fewer human parasites than the latter class.

In form the Trematoda are generally flattened and elongate, more rarely cylindrical, conical or irregular, with plane ventral surface on which are located the sexual pores and arched dorsum. The mouth is at or near the anterior tip of the body and the excretory pore is similarly related to the posterior end. The mouth is nearly always surrounded by an oral sucker, and other suckers may occur on the ventral surface, at the posterior end, or more rarely on the margin or dorsal surface. In connection with the suckers chitinous hooks or anchors are found as additional organs of attachment, and the exterior of the body is often covered more or less completely by scales or spines of varying form and size. Most flukes are comparatively insignificant in size, measuring only a few (1 to 15) millimetres in length, though rare species largely exceed both limits.

A cross section shows that a body cavity is wanting. The trematodes belong to the group of forms in which the space between all organs is filled up by parenchymatous tissue, giving a firm consistence to the mass. The exterior is bounded by a homogeneous membrane of varying thickness known as the cuticula, which actually is formed by the fused bases of cells lying deeper in the tissue, but which presents the appearance of a basement membrane. It was formerly construed as such, and the trematodes were believed to be without an epithelial covering in the adult condition. As a matter of fact the pyriform epithelial cells lie in bunches between or within the diagonal muscles, and are connected by numerous fine processes with the basal surface of the so called cuticula. Some of these cells are especially developed as unicellular glands.

The dermomuscular sac lies just within the cuticula and consists of layers of circular, longitudinal, and diagonal fibres which surround the body, though of varying thickness in different regions. Running obliquely from one surface to the other occur also dorsoventral or parenchymatous muscles which are inserted on the cuticula. Especial development of the muscular layers is found in the suckers, which consist of muscle fibres extending in three directions and designated as equatorial, meridional, and radial; these correspond to the circular, longitudinal, and dorsoventral muscles respectively. In addition one finds a special set of muscles radiating from the sucker through the tissue. In certain cases at least special mus 'es are developed in connection with the reproductive organs, with the hooks, and even with the surface spines, as in the common liver fluke. The high development of the muscular system, associated with the absence of special skeletal structures, combine to make the form of the flukes extremely mobile and variable. Locomotion is achieved by means of the body musculature and the suckers, aided in rare cases by the cuticular spines already mentioned.

An alimentary canal is always present and forms the ultimate distinctive feature between Trematoda and Cestoda. In all cases it has but a single opening, the mouth, which lies at the anterior tip of the body, or more rarely on the ventral surface and in all higher forms is surrounded by the oral sucker (*O*, Fig. 4772). In lower members of the group, two or more suckers may lie near the oral opening or the latter may be entirely unarmed. In form the alimentary canal may be rhabdocœl, though much more frequently it is of the triclad type. In the latter case one can distinguish an initial unpaired region variable in length, which extends posteriad from the oral opening and is called the œsophagus. It is thin-walled and not digestive in function, though frequently numbers of unicellular salivary glands are connected with it. Near its oral end a prominent sphincter muscle forms a bulbous mass known as the pharynx. By its action the oral sucker is closed posteriorly to act as a simple organ of prehension, or stands in open communication with the canal, for which it serves as an aid in the ingestion of food.

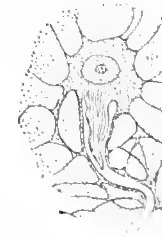

FIG. 4773. Flame Cell and Excretory Tubule of *Azygia tereticollis* (R.) × 700. (After Looss.)

The simple œsophagus divides into two intestinal crura (*I*, Fig. 4772), which form the digestive and absorptive region of the canal. They are blind sacs, usually symmetrically placed right and left, but of variable length and character. In some genera they are so short as not to reach the sides of the body; in other cases they extend to the posterior end, and may even be connected by several commissures or anastomoses. Usually the crura are of uniform calibre throughout, and yet in some genera they manifest an irregular wavy outline, or even possess numerous lateral diverticula which may branch again and give the system a dendritic aspect. The endoparasitic forms subsist on the intestinal contents and secretions of the host, but also ingest epithelial cells and blood, thus giving rise in some cases to severe hepatic or intestinal disturbances, the gravity of which is proportionate to the extent of the invasion.

The excretory system agrees in general with that of the Cestoda. One finds a variable number of primitive nephridia or "flame cells" (Fig. 4773), scattered throughout the tissue. These cells are stellate in form, with a huge bunch of cilia which lie on one side in a narrow canal. The constant motion of the group of cilia simulates the flickering of a candle flame, whence the name. The tubules from these flame cells unite into larger ducts, and ultimately combine in a single vessel, which opens at the posterior end of the body by a simple excretory pore (*p*, Fig. 4774). The final vessel may be short and expanded or a longer median canal. In both cases it apparently functions as an excretory reservoir or bladder (*ves*, Fig. 4774). The system, which was formerly called a water vascular system, contains a clear fluid, sometimes slightly tinted, with occasional granules or concretions. It is produced by the activity probably of the terminal cells, the cilia of which serve to maintain movement. The presence of uric acid in the fluid is sufficient evidence of its excretory nature.

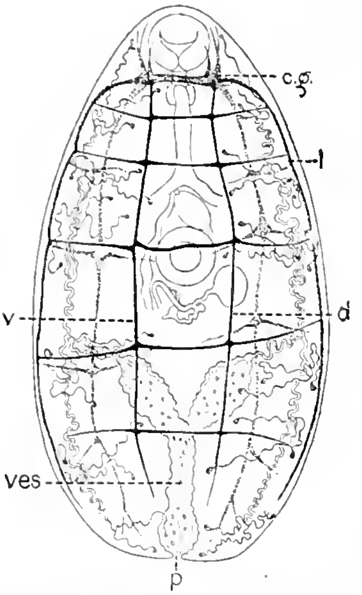

FIG. 4774.—Nervous and Excretory Systems in *Opisthioglyphe endoloba* (Duj.). *c.g.*, Cerebral ganglion; *d*, dorsal, *l*, lateral, *v*, ventral nerve trunks; *p*, excretory pore; *ves*, excretory bladder. × 30. (After Looss.)

The nervous system is poorly developed in accord with the parasitic habit of the group. It consists of two small lateral aggregations of ganglion cells (*c.g.*, Fig. 4774) near the pharynx which are joined by a ring of fibres that encircles the œsophagus, and of nerves extending anteriad and posteriad from these ganglia. The three pairs passing anteriad are short and innervate the oral sucker with adjacent dermal areas, muscles, and primitive sense organs. The posterior nerves form dorsal, (*d*), lateral (*l*), and ventral (*v*) paired cords. The ventral nerve cords are much the most prominently developed; they join each other near the posterior end as do also the dorsal cords. Circular commissures at somewhat regular intervals unite all three pairs of nerves, and ganglion cells occur most frequently at the points of union, though also rarely elsewhere in the course of the nerves. A dermal nerve plexus is at least often present, and stands in immediate connection with the main nerve trunks. Sense organs, of the most primitive sort, occur in the skin, while in the free swimming larvæ as well as in ectoparasitic forms simple eye spots are found. Other sense organs are not known.

Reproductive System.—The Trematoda are all but universally hermaphroditic, and possess highly complicated organs of reproduction. One of the human parasites illustrates the rare secondary condition of separate sexes, and will be considered under the appropriate heading; here it is sufficient to outline the general conditions.

The testes (*T*, *T*, Fig. 4772) are usually two in number, symmetrical in size and location, although there may be but a single one, or on the other hand a series of several. These organs are commonly round or oval in outline, with frequent variations toward a lobed condition, or even to a dendritic form. The two vasa efferentia unite sooner or later into a single vas deferens, which may or may not possess an enlarged region used as a seminal vesicle. The duct opens on the surface of the body, or into a genital cloaca at the common genital pore, and the terminal portion of the canal may form by eversion a protrusible copulatory organ. More frequently this region possesses a highly developed muscular organ known as the cirrus, and this with or without the seminal vesicle may be enclosed in a sac denominated the cirrus pouch, and provided with unicellular glands (prostata). When highly developed this copulatory apparatus forms a conspicuous organ, and, as has recently been elucidated by Looss, constitutes a valuable taxonomic character.

The female reproductive organs show an unusual specialization in the separation of the germarium, often incorrectly denominated the ovarium, from the vitellaria or yolk glands. The germarium (*G*, Fig. 4775) is small, located ordinarily in front of the testes, and usually round or oval in outline, although it may also be dendritic in form. The vitellaria are paired, highly lobed or dendritic in form, and extended usually along the sides of the body lateral to the intestinal crura. Their extent is of importance in specific determinations. The duct from each vitelline gland tends toward the germarium, and near this organ unites with that from the opposite side in a common yolk or vitelline duct, on which at the junction there is at times an enlargement known as the vitelline reservoir. The short germ duct, coming from the germarium, and the common yolk duct, unite to form a short, slightly expanded tube known as the ootype on the sides of which are found unicellular glands, often crowded together into a mass and collectively denominated the shell gland (*Sg*, Fig. 4775). From the ootype a short inconspicuous canal rises to the dorsal surface; this organ, called Laurer's canal (*L.C.*), is clearly rudimentary, and its significance is not beyond dispute, although it is usually homologized with the vagina of ectoparasitic forms; and, according to recent observations, still functions as such in rare cases. It may bear near the proximal end a bulbous lateral expansion, the seminal receptacle (*R*).

The ootype expands immediately beyond the shell gland to form the uterus (*Ut*), which as a long convoluted tube fills the major portion of the body with its coils crowded with opaque brown-shelled eggs. In the portion of the uterus which lies near the ootype there is usually a mass of sperm, so that the region has been called the uterine seminal receptacle. The uterus terminates in short heavy-walled region devoid of eggs, known as the metraterm. This lies alongside of the cirrus pouch, and opens at the female genital pore on the surface of the body, or into the genital cloaca and serves to receive the cirrus in coition. In these forms cross fertilization is the rule, and cases have been observed in which one individual only functioned as the male as well as such in which both were thus functional. In a few instances self-impregnation has been found. The genital pore lies ordinarily in the median line near the ventral sucker, or between it and the fork of the alimentary canal; but a marginal position, or one near the oral sucker, or even at the posterior end of the body, is also to be found.

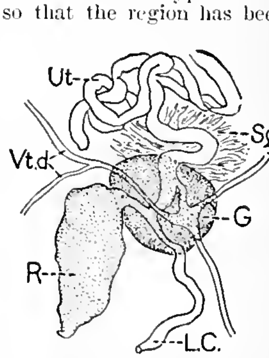

FIG. 4775.—Female Sexual Organs of *Opisthorchis pseudofelineus* Ward. Highly magnified to show relation of ducts. *G*, Germarium; *L.C.*, Laurer's canal; *R*, seminal receptacle; *Sg*, shell gland; *Ut*, beginning of uterus; *Vt.d*, vitelline ducts. (Original.)

In the arrangement of the reproductive organs one finds the double condition designated sexual amphitypy, in which one individual is, as it were, the mirror image of the other. Usually one can be designated as having the normal arrangement, but the relative frequency may be such that neither can be said to be more typical than the other. Such a reversed arrangement was first observed among the Opisthorchiinæ, where it seems to be very common; it has also been shown to exist among the Dicrocœliinæ, and the difference in Paragonimus Westermanii referred to later (Figs. 4782, 4784) may be explained in the same way.

This description obtains for the endoparasitic forms, particularly for the Fasciolidæ, which are of especial importance here. In other families, especially among the ectoparasites, somewhat radical differences from the plan outlined may be observed.

The egg of the Trematoda is more or less oval or ellipsoidal, rarely flattened asymmetrically. It is provided with a heavy chitinous shell which is transparent when first formed, but darkens soon in the first coils of the uterus to a deep yellowish-brown, which is almost entirely opaque. In ectoparasitic forms the egg shell possesses a polar filament by which it is attached when deposited; but this is not present in endoparasitic forms. At most one finds an irregular, insignificant protuberance at one pole, such as is present in *Schistosoma hæmatobium.* The shell regularly possesses a cap or lid which is sprung at the appropriate time to allow of the escape of the enclosed embryo. Such eggs may be found in the waste of the body, excreta, or sputa, or may occur adventitiously in various tissues. Under such circumstances they have in the past been diagnosed as coccidia.

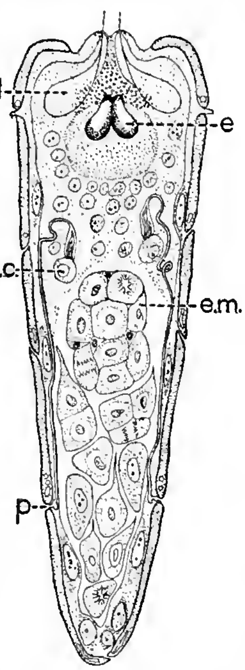

FIG. 4776.—Miracidium of *Fasciola hepatica* (L.); in cross section, showing eye spot (*e*), embryonic cell masses (*e.m.*), flame cells (*fl.c.*), cephalic glands (*gl.*), and excretory pore (*p*). Much magnified. (After Coe.)

Development.—When first formed the shell contains the single fertilized egg cell surrounded by a mass of highly granular yolk cells. The latter may be distinct or may be already broken down into an indistinct granular mass. This serves for the nutrition of the embryo during early development. The cleavage of the fertilized ovum begins at once, and ordinarily proceeds so as to bring the embryo to development at the time when the egg, extruded from the uterus of the parent worm, is carried into the external world with the waste products of the host. This is simple since the normal seat of the parasite is the alimentary canal, or some of its outgrowths, liver, lungs, etc., and the eggs are distributed with sputa, fæces, or rarely urine.

The modified environment brings about the opening of the egg shell and the escape of the embryo, which follow experimentally when the ripe eggs are brought into water at suitable temperature. The embryo (Fig. 4776), which is designated a miracidium, is somewhat elongated in form, with a conical tip, and sometimes also a sharp boring spine at the anterior end. The ectoderm is composed of large cells and is ciliated. One may distinguish also a pair of flame cells (*fl.c*, Fig. 4776), or primitive excretory organs, and a rudimentary **X**-shaped eye spot (*e*). In the interior the cells are smaller and are arranged irregularly about a cavity into which they are set free singly or in groups. These do not become prominent until the miracidium has attained its location in a new host, and this, which it seeks at once on emergence from the egg shell, is almost universally a mollusk. Embedded in the tissue of the mollusk, which is known as the secondary or larval host, the miracidium loses its coating of cilia, its eye

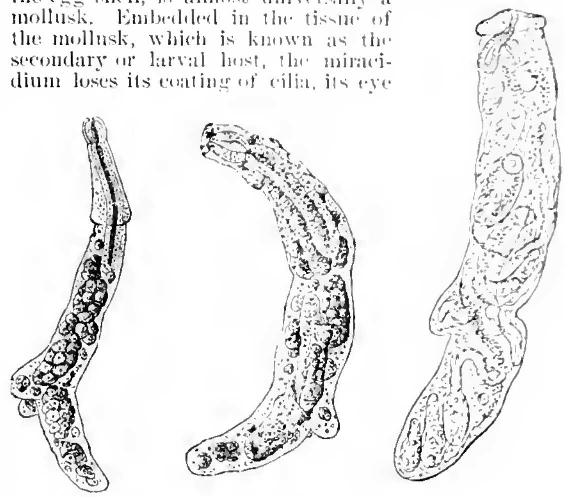

FIG. 4777.—Rediæ of *Fasciola hepatica* (L.). × 120. *A*, Young specimen with cell masses just forming; *B*, older individual with young rediæ developing; *C*, form with developing cercariæ. (After Leuckart.)

spot and its special form becoming a mere irregular sac, now designated as the sporocyst, in which one finds cell masses crowding the cavity and developing into a new generation. In the ordinary case their form is that known as the redia, and when developed they escape from the sporocyst only to enter upon a similar method of reproduction, which gives rise to another new generation. In structure the redia (Fig. 4777) is characterized by an elongate form, a mouth with single oral sucker, a rhabdocœl alimentary canal, two short locomotor protuberances, and an orifice known as the birth opening through which the new brood escapes.

This new generation originates as did that in the sporocyst from cells or cell masses set free from the wall of the cavity. The form developing therefrom may be a redia like that which produced it; more often it is still another new form, known as a cercaria, and in some cases the cercaria may even be produced directly from the first generation, the miracidium metamorphosed into a sporocyst or a redia. The form of the full-grown cercaria (Fig. 4778) is sufficiently characteristic to allow of its easy recognition. It is somewhat broader than the redia, possesses a ventral sucker as well as an oral, a triclad alimentary canal, and an active caudal appendage for swimming, though in some forms designated as varieties of this stage this tail may be wanting or modified. The cercaria is in fact the young distome, supplied with an organ of locomotion when some part of the life cycle is to be spent in the open. Now, if not before, the young fluke is ready for the change of hosts which accompanies its attainment of the adult condition. The transfer may be passive or it may be associated with an active migration from the secondary host and a period of existence in the open water before the primary host is reached. Once that the latter is attained,

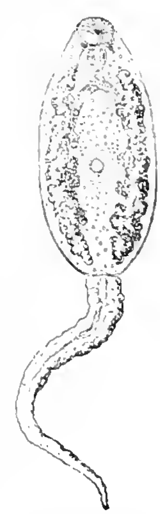

FIG. 4778.—Free Cercaria of *Fasciola hepatica* (L.). Magnified. (After Leuckart.)

the tail of the cercaria is thrown off and the further development to the adult form is growth, chiefly of the reproductive organs which were present before only in rudimentary form. An encysted stage frequently intervenes. This the cercaria attains by burrowing into the tissue of some animal, or by settling upon the surface of some plant or other object. In the latter case the cyst is formed of the expressed secretion of dermal glands which hardens about the cercaria, which now has cast off its tail. In either event the digestive fluids of the final host are the means of liberating the worm from its cyst to enter upon the final stage of its career.

Great differences in detail are found in different species. The following table, taken from Hertwig, exhibits in synoptic form the principal lines of development. Individual features connected with the species which occur as human parasites may be found under the appropriate headings. The entire process was formerly regarded as the true alternation of a sexual generation, the adult worm, with one or more asexual generations, sporocyst, and redia; but at present the reproduction of the latter is regarded rather as premature parthenogenesis or pædogenesis, and the alternation is called alloiogenesis. Some authors regard it, however, as merely a complicated metamorphosis, which is distributed over several generations. The transportation of the parasite from one host to another may be passive, as when the encysted form is eaten and set free in the alimentary canal of the new host by digestion, or it may be active in that the free swimming larva is engulfed with drinking-water by chance, or bores its way into the body of the water-inhabiting mollusk which it seeks out.

secondary host is somewhat narrow, so that not only is a direct infection from the adult fluke contrary to all experience, but also the introduction of the adult and the dissemination of the ova in a new region can be followed by the permanent establishment of the parasite only when a suitable larval or secondary host is available. The sheep liver fluke, *Fasciola hepatica*, has thus secured a footing in certain regions of the United States, and has become an important factor in the handling of domestic animals. It remains to be seen whether the human blood fluke, *Schistosoma hæmatobium*, probably introduced from Africa to the southeastern States, and the Asiatic fluke, *Opisthorchis sinensis*, undoubtedly brought to the Pacific coast from the East, will establish themselves similarly to the detriment of the human species.

The encysted cercaria or immature distome occurs rarely in mammals, *e.g.*, the pig, more frequently in amphibians and fishes and generally among invertebrates. The mature trematodes are parasitic only among vertebrates; the ectoparasitic forms inhabiting chiefly the skin or gills of aquatic species, and the endoparasitic forms occurring largely in the alimentary canal, though almost all organs may harbor them at times. Next to the canal, its adnexa, the lungs and liver, are favorite seats of these parasites, but the latter are not wanting in the genito-urinary ducts, where for instance in birds they occur so frequently as to be occasionally enclosed within the egg shell during its formation and are subsequently discovered there. While the flukes usually move freely about in the cavity of the affected organ, they are in some cases more or less completely encysted in its substance. Thus the Asiatic lung fluke, *Paragonimus Westermanii*, is found in pairs in pulmonary cysts, and in rare instances such an association in pairs is connected with the secondarily acquired diœcious condition of the individual species.

Development of the Distomes.

Third generation...	....	....	....	....	Cercaria........... Encysted distome.. Sexually mature distome.	Water. Host II. Host III.

Thus far only thirteen species of fluke have been listed as human parasites; they are as follows:

Family: Paramphistomidæ.
  Gastrodiscus hominis.
Family: Fasciolidæ.
  Fasciola hepatica. Species recorded in United States of America.
  Fasciola angusta.
  Fasciolopsis Buski.
  Fasciolopsis Rathouisi.
  Paragonimus Westermanii.—Species recorded in United States of America.
  Opisthorchis felineus.
  Opisthorchis sinensis.—Recorded from man in United States of America.
  Opisthorchis noverca.
  Metorchis truncatus.
  Heterophyes heterophyes.
  Dicrocœlium lanceatum.—Species recorded in United States of America.
Family: Schistosomidæ.
  Schistosoma hæmatobium.—Recorded from man in United States of America.

It thus appears that only five species have ever been found in the United States, and that but two of these have been recorded from the human host. It may be further noted that of these two, one (*Schistosoma hæmatobium*) was certainly acquired in other lands and apparently has not gained a footing in our own, while the same is probably true of the other, leaving for the human host not a single record of trematode infection originating within the limits of the United States.

The earlier stages in the life history, sporocyst and redia, occur only in mollusks, and the selection of the

The effects of parasitism have already been discussed (see *Parasites*); special features as well as means of treatment are treated under individual forms. The human parasites belonging to this group, as already recorded, are too few in number of species to call for a special key as an aid to identification.

Taxonomy.—Valuable recent work by Braun and Looss on the taxonomy of the group makes it possible to give a reasonable system. Only the parts dealing with human parasites will be particularly considered.

Order Heterocotylea.—Ectoparasitic forms with powerfully developed organs of attachment; excretory organs open separately on the dorsum; development direct. Parasitic on body and gills of fishes chiefly. No human parasites.

Order Aspidocotylea.—Endoparasitic Trematoda of simple organization with large ventral organ of attachment; excretory organs open by a single posterior pore; development direct. No human parasites.

Order Malacocotylea.—Trematoda with one or two suckers, or rarely accessory lateral suckers also, for attachment; no chitinous organs of attachment. Intestine usually forked and mouth anterior; mostly hermaphroditic with sexual pore ventral; excretory pore posterior. Always endoparasitic in vertebrata. According to mode of development divisible into two groups:

(*a*) *Metastatica*. Development without alternation of generations, but with two larval forms and change of hosts. No human parasites.

(*b*) *Digenea*. Development complicated by alternation of asexual generations (sporocyst, redia) with sexual generation. One or more changes of host. All human trematode parasites fall in a few families of this very large and varied group, viz.: Paramphistomidæ, Fasciolidæ, Schisto somidæ.

The family of the Paramphistomidæ is characterized by a terminal sucker, dorsal to which the excretory pore is located. The genital pore lies in the midventral line in the anterior third of the body; the pharynx is far forward and ordinarily designated the oral sucker; the intestinal branches are always simple, hermaphroditic. Only one genus is of interest here:

Gastrodiscus Leuckart.—Paramphistomidæ with slender anterior region and large discoidal posterior region, which is concave ventrally. The small terminal sucker lies on the posterior ventral margin of this concavity. Pharynx with two outpocketings.

Various species occur in the alimentary canal of the horse and cattle in Egypt and India; one has been found parasitic in man.

Gastrodiscus hominis (Lewis and McConnell 1876.)—(Syn.: *Amphistomum hominis* Lewis and McConnell 1876.) Body 5–8 mm. long, 3–4 mm. broad, reddish when living. Genital pore at bifurcation of intestinal crura. Eggs oval, 0.150 mm. long, 0.072 mm. broad.

The structure of this species is only imperfectly known. It has been found twice in Assam and India in the cæcum and colon of natives who had died from cholera. Although present in large numbers in these cases Braun regards it as undoubtedly an occasional parasite, the normal host of which is as yet unknown. Giles, however, found it frequently in Assam, and according to Leuckart never more than twelve individuals in a single host, which militates against the idea that it was only an occasional parasite.

The family of the Fasciolidæ is characterized by the presence of oral and ventral suckers, by the genital pore ventral, rarely lateral or terminal; always hermaphroditic, two testes, one germarium, with receptaculum seminis or Laurer's canal, or both, and with paired lateral often highly branched vitellaria.

The majority of human trematode parasites fall within the limits of this very large and highly differentiated family.

Fasciola Linnæus 1758.—Large Fasciolidæ with leaf-shaped body, the anterior end of which has the form of a conical cap or tip, distinctly set off from the posterior region; acetabulum on the boundary of the two regions, large and powerful. Œsophagus short, with pharynx; intestinal crura reaching almost to posterior end near the median line of the body, with short branches on median side and with long, highly dendritic branches on lateral side. Excretory system much branched, reservoir a long median sac. Genital pore in midventral line in front of acetabulum; germarium in front of testes and transverse yolk duct, highly dendritic, as also the testes which are located obliquely behind one another and posterior to transverse yolk duct; uterus in form of a rosette in front of germ glands; vitellaria on sides even to posterior end, well developed. Laurer's canal present, receptaculum seminis wanting. Eggs large, not numerous, developing after deposition. Parasitic in gall ducts of herbivora, more rarely omnivora.

Fasciola hepatica L. 1758.—(Syn.: *Distoma hepaticum* Retzius 1786; *Fasciola humana* Gmelin 1790. *Distomum cariæ* Sonsino 1890; *Cladocœlium hepaticum* Stossich 1892). Body flattened like a leaf (Fig. 4779), reddish-brown in color, 20–30, rarely 35–50 mm. long, 5 or 8–13 mm. broad, with anterior region 4–5 mm. long, and distinctly set off from the posterior; posterior extremity bluntly pointed. Dermal spines over entire body except a small area near the posterior end. Oral sucker terminal, nearly spherical, about 1 mm. in diameter, acetabulum at junction of two regions about 1.6 mm. in diameter, spherical with triangular aperture. Pharyngeal bulb covering nearly entire œsophagus, intestinal crura, with numerous dendritic branches directed laterad; vitellaria, lateral, dendritic, both dorsal and ventral of intestine. Germarium and testes both dendritic, former anterior, latter posterior to transverse yolk duct and side by side. Eggs oval, 0.130–0.145 mm. long by 0.07–0.09 mm. broad, deposited before commencement of cleavage.

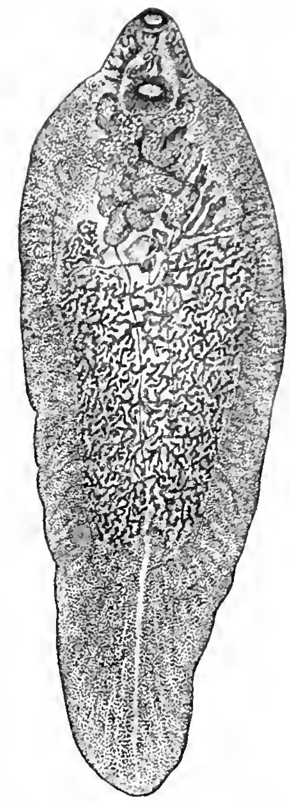

Fig. 4779.—*Fasciola hepatica* (L.). American Specimen from Cattle. Magnified. (After Stiles.)

This species is parasitic in the biliary ducts of sheep especially, but it also occurs in many other ruminants, cattle, goat, horse, ass, deer, antelope, camel, as well as in the kangaroo, squirrel, beaver, rabbit, guinea-pig, and man.

Life History.—The complicated development of this form has been elucidated chiefly by the researches of Leuckart and Thomas. The eggs must remain some weeks in water at the ordinary temperature to complete the development of the miracidium, which on being set free seeks out a small snail (*Limnæa truncatula* Müll. = *L. minuta* Drap.) that is commonly found in small pools or on partially flooded meadows.

The miracidium (Fig. 4776) attaches itself to some fleshy region of the snail, throws off its ciliary coating and then penetrates to the snail's liver, where it becomes a mere sac filled with masses of developing germ cells. This sac, known as the sporocyst, produces rediæ, which remain in the same host, and sometimes give rise to a second generation of rediæ (Fig. 4777, *A*, *B*). The cercariæ (Fig. 4777, *C*, and Fig. 4778), which are produced by rediæ sooner or later, make their way out of the snail and encyst on blades of grass, with which they attain the final host in its food. The young distome set free in the stomach is small, transparent, without separate regions of the body, and with only rudiments of the reproductive organs. It makes its way far up into the gall ducts of the liver and there attains its maximum size. The life of the adult lasts probably not more than a year, but infection of the final host takes place most commonly in the early fall or late summer. In the spring the eggs are most abundantly distributed over the meadows, with the excrement of the sheep. Lutz found that in the Hawaiian Islands *Limnæa oahuensis* and *L. rubella* served as intermediate hosts. None of these species occur in the United States, and the species which actually serves as larval host is as yet unknown.

The common liver fluke is distributed over nearly the whole of Europe; it also occurs in North and South America and Australia, where it has been introduced in domestic animals. Records of its occurrence in Africa and Asia are undoubtedly due, in part at least, to confusion with closely related species, and must be verified before they can be accepted as final.

Pathology.—Known since the middle of the sixteenth century, the common liver fluke was first positively identified as a human parasite by Pallas in 1760, although earlier reports of Malphighi and others probably concern this species. Between twenty and thirty well-established cases are on record; they have been compiled and discussed by Leuckart, Blanchard, and Moniez. All degrees of infection are represented, from such as were so slight as to have been discovered by accident to such as were the direct cause of death. In the bile ducts the flukes have only rarely evoked serious symptoms, though in two or three cases fatal termination was due to obduction of the ductus hepaticus s. choledochus by one of these flukes. In the majority of cases the parasite produced no noticeable symptoms, evidently due to the presence of only a small number of individuals, and it is possible that infection is more general than heretofore believed. At any rate Kratter proclaims it to be frequent in Dalmatia, and Perroncito found distome eggs frequently in fæcal examinations among laborers at the St. Gothard tunnel. Even in severer cases the symptoms are general, indicating only some affection of the liver. Thus pain in that organ, swelling and icterus have been mentioned by different observers. In the majority of cases, also, the parasite has not been found in its normal seat, the liver, but as an erratic in the lungs, in blood-vessels, in subcutaneous tumors, and elsewhere. This is not strange in the light of Railliet's demonstration that the liver fluke subsists on blood; thus young flukes especially may make their way into the circulatory system and be carried by the blood current into any part of the body.

Such occurrences of erratic individuals give some basis for the interpretation of other doubtful organisms as also belonging to this species, and many authors regard the *Hexathyridium venarum*, reported by Treutler in 1793, from the tibial vein of a young man which ruptured while the patient was bathing, as an erratic specimen of *Fasciola hepatica*. Leuckart, however, says there is more reason to regard it as a free living planarian, which did not actually come from the vein, but was obtained accidentally from the water.

These cases of parasitism of *Fasciola hepatica* in man have been reported largely in European countries, the only one outside being from Australia. The record of Chabert in 1852, that this species occurred in Boston in company with *Tænia*, rests upon an erroneous view regarding the isolated segments of the tapeworm, as Leuckart and Cobbold have clearly shown. Nevertheless in those parts of this country where *Fasciola hepatica* is common, cases of human infection are likely to occur. This takes place supposedly through the consumption of cress, lettuce, and other uncooked plants which have been grown in low, damp regions where infected snails were present, and where consequently the liberated cercariæ had opportunity to encyst upon the leaves. The evident infrequency of such an occurrence coincides with the usually mild infection in man as compared with the domesticated animals.

Associated with the light infection and also with its infrequency is the absence of any definite symptoms in the human host which denote the presence of the parasite. As already explained, the infection usually becomes known only by chance; but even were it determined by accidental discovery of the eggs in fæcal examinations, no special means could be suggested to bring about the evacuation of the parasite, which lies deep in the ducts of the liver, and is held against retrograde movements by the thick-set, retrorse spines that cover nearly the entire body. So far as can be determined the life of the adult lasts not more than about a year. Care in the use of uncooked plants should be exercised in all regions where these flukes are abundant.

Agamodistomum ophthalmobium (Diesing 1850).—(Syn., *D. oculi humani* Gescheidt 1833; [?] *Monostomum lentis* Gescheidt 1833; *Distomum ophthalmobium* Diesing 1850.) Two cases of some interest may be noted here in which the parasites are too poorly known to allow of exact identification. In one case four immature distomes were removed from the eye of a five months' child with lenticular cataract with partial opacity of the capsule. The other case was that of an elderly woman from whose eye eight so-called monostomes were removed from the lens substance. The descriptions do not enable one to determine the species or to assert the identity of the forms. They were undoubtedly erratic parasites, and it seems highly probable that in the former case at least the parasite was the young form of one of the liver flukes of man. Several authors regard them as very young lancet flukes (*Dicrocœlium lanceatum*) which had strayed into this unusual location. There is every ground for believing them to be pathogenic, as are other species in the eyes of other vertebrates (*e.g.*, fish), and a repetition of the occurrence on the part of the erratic young of the same or other species may be confidently predicted. (For full data on these cases compare Stiles 1902.)

Fasciola angusta (Railliet 1895).—(Syn: *F. hepatica* var. *angusta* Railliet 1895). Body flat, linguiform, with sides nearly parallel and slenderer than *F. hepatica*. Length, 26–38 mm.; breadth, 6–8 mm. Anterior region short. Posterior end broadly rounded. Acetabulum large, prominent, only 2 mm. from anterior tip of body. Eggs oval, 0.143 to 0.151 mm. by 0.082 to 0.088 mm.

Railliet described this form from the liver of cattle slaughtered in Senegal, and at the same time called attention to a case recorded by Gouvea, a physician in Rio Janeiro. The patient, a French marine officer, suffered from fever, cough, and blood spitting. The only pulmonary defect demonstrable was a sharply defined spot at the base of the left lung. Some twenty days later he coughed up a fluke, which probably belonged to this species, and was acquired during a residence in Senegambia. Blanchard regards it, however, as *F. gigantica* Cobb, mentioned below.

The case demonstrates also the susceptibility of man to other species of the genus Fasciola as well as to that ordinarily known, and renders it advisable to make brief mention here of the other species of this genus which are likely to be encountered in various regions.

Very closely related to the last species are *Fasciola ægyptiaca* Looss, which occurs in the domesticated herbivora of Egypt, and *F. gigantica* Cobbold, which was originally described from the liver of the giraffe, but which, according to Blanchard, occurs in the cattle of Senegambia and other regions in Africa. Probably these species may be introduced under favorable chances into the human host as well as the related species already described.

More important for American physicians is the allied native species which is so widely distributed on this continent. Although it has not yet been reported as a human parasite, the probability of its occurrence as such is sufficiently immediate to call for its description here.

Fasciola magna (Bassi 1875) Stiles 1894.—(Syn.: *Distomum magnum* Bassi 1875; *F. carnosa* Hassall 1891; *F. americana* Hassall 1891; *D. texanicum* Francis 1891; *D. crassum* [in part] Leidy 1891; *Cladocœlium giganteum* [in part] Stossich 1892.) Body flesh-colored when alive, broad, thick; much larger and thicker than *F. hepatica*; length, 23–100 mm.; breadth, 11–26 mm.; thickness, 2–4.5 mm. The conical anterior part is not distinctly set off from the posterior. The posterior end is bluntly rounded, and margin more convex. In general the structure is very similar to *F. hepatica*, except that the œsophagus is longer, one-and-a-half to three times as long as the pharynx, the intestines more branched, and the yolk glands confined to the ventral side of the intestine; eggs oval, 0.109–0.168 mm. long by 0.075–0.096 mm. wide.

This fluke is found in cysts in the liver and lungs of cattle and of several species of deer, and is very widely distributed, occurring on the authority of various persons in Texas, Arkansas, California, Iowa, Illinois, New York (Adirondacks), and Italy. It is probably present in most parts of this country. In importance it stands hardly second to *F. hepatica*, but of its life history nothing is definitely known. Its close relationship to other species which have been reported occasionally from the human host in Europe indicates that this species also may adopt the same rôle here when circumstances favor.

Fasciolopsis Looss.—Fasciolinæ without distinct anterior and posterior regions. Cuticula smooth. Acetabulum powerfully developed with cavity extended posteriad as sacculate invagination and much larger than oral sucker. Intestinal crura simple, slender, wavy but without evaginations. Testes dendritic, with branches growing smaller toward distal ends. Cirrus pouch very long, cylindrical, containing spiral tubular seminal vesicle with peculiar cæcal appendage. Cirrus closely covered with fine spines. In alimentary canal of mammals.

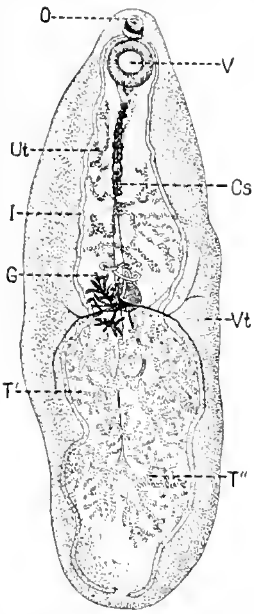

FIG. 4780.—*Fasciolopsis Buski* (Lank.). *Cs*, Cirrus sac; other abbreviations as before. × 3. (After Odhner.)

Fasciolopsis Buski (Lankester 1857).—(Syn.: *Distomum Buski* Lank. 1857; *Distoma crassum* Busk 1859, nec v. Sieb. 1836). Length, 24–37 mm., average about 30; breadth, 5.5–12 mm., average, 9 mm.; greatest thickness, 1.5 mm.; body (Fig. 4780) flattened, linguiform, anterior region tapering, but not sharply marked off from posterior body. Anterior sucker 0.5 mm. in diameter, acetabulum separated by not more than its diameter (1.6–2 mm.) from anterior end, with deep triangular lumen. Pharynx large, powerful; prepharynx present; œsophagus very short; intestinal crura slender, extending to extreme posterior end in three shallow curves. Testes dendritic one behind the other in median field, and both posterior to transverse yolk duct; cirrus sac median, cylindrical, much elongated, enclosing long spiral seminal vesicle with lateral elongate cæcal appendage. Germarium small, dendritic, anterior to testes, and to transverse yolk duct; Laurer's canal present, receptaculum seminis wanting; uterus in scanty irregular open coils, anterior to ovary; yolk glands lateral with numerous very small acini extending length of body; genital pore immediately at anterior margin of acetabulum, cirrus covered with many fine spines; eggs numerous, 0.12–0.126 mm. in length, 0.077 mm. in breadth; similar to those of *Fasciola hepatica*.

Eight positive and several uncertain cases of the occurrence of this species are on record. They are all from southern or eastern Asia and all concern the human host. The parasite occurs in the duodenum according to Busk, and the symptoms of Cobbold's and Olhner's cases pointed unmistakably to this as an intestinal parasite. No facts on the life history are recorded as yet. In 1891 Leidy reported as belonging to this species specimens received from New York, Arkansas, and Texas, where they were collected from the liver of a doe in the first case and from cattle in the other two instances. The species he had under observation, however, was actually *Fasciola magna*, and there is no evidence that *Fasciolopsis Buski* has been found on this continent, although its occasional introduction by the Chinese is not a remote contingency in view of the known facts regarding other species (*cf. Paragonimus Westermanii* and *Opisthorchis sinensis*).

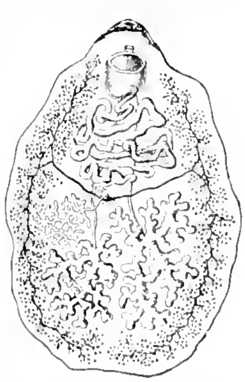

FIG. 4781.—*Fasciolopsis Rathouisi* (Poirier). × 2. (From Leuckart, after Poirier.)

Fasciolopsis Rathouisi (Poirier 1887).—(Syn.: *Distomum Rathouisi* Poirier 1887.) Length 25 mm., breadth 16 mm., oval, with indistinctly marked anterior region (Fig. 7481). Cuticula smooth. Oral sucker 1.5 mm., ventral 2 mm. in diameter. Intestinal crura unbranched; germ gland dendritic, posterior to transverse yolk duct; vitellaria lateral, not joined posteriad; uterus in centre of anterior half of body; genital pore just in front of acetabulum. Eggs 0.150 by 0.08 mm.

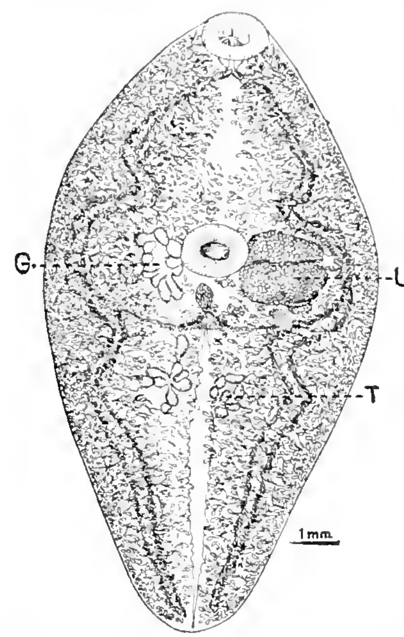

FIG. 4782.—*Paragonimus Westermanii* (Kerb.) in Ventral Aspect. American specimen from dog. Note reverse position of reproductive organs as compared with Fig. 4784. × 5. (Original.)

Nothing is known of the development of this species. It has been observed only once in a Chinese woman, who vomited the specimens after violent pain in the region of the liver. Possibly the cases reported by Blanchard from correspondence with P. Manson belong to this species.

Paragonimus Braun 1899.—Body thick, oval, or spindle-shaped, and nearly circular in transsection. Cuticula spinous. Acetabulum near centre of body. Alimentary canal with prominent pharynx, very short œsophagus, and intestinal crura extending in irregular zigzag to posterior end. Excretory bladder large, extending nearly to pharynx. Genital pore lateral near acetabulum. Special copulatory organs wanting. Testes dendritic, right and left in posterior region. Germarium also dendritic, anterior to left testis. Receptaculum seminis lacking. Laurer's canal present. Vitellaria extensive, on side of body almost the entire length and dorsal also almost to median line. Uterus scantily developed as coil lateral to and near acetabulum. Eggs large. Usually by pairs in cysts in lungs of mammals.

Paragonimus Westermanii (Kerbert 1878).—(Syn.: *Distoma Westermanii* Kerbert 1878; *D. Ringeri* Cobbold 1880; *D. pulmonale* Baelz 1883, *D. pulmonis* K. S. and Y. 1881; *Mesogonimus Westermanni* Railliet 1890.) Length 8–16 or even 20 mm., breadth 4–8 mm., body thick and plump, posterior end more pointed, ventral surface more flattened (Fig. 7482); color, deep red or reddish brown when alive, or dark gray in alcoholic material, with conspicuous black dendritic acini of the yolk gland along the side. Cuticula spinous; oral sucker 0.53–0.75 mm. (Leuckart), or 0.86–1.2, or even 1.4 mm. (Ward). Acetabulum 0.6–0.75 mm. (Leuckart), 0.75–1.02 mm. (Ward); slightly larger than oral sucker, situated anterior to middle of body; œsophagus short, intestinal cæca wavy, with irregular outline, extending to posterior end of body. Germarium branched, posterior to acetabulum, lateral, opposite the lobate shell gland, which lies directly in front of the condensed uterus. Yolk glands highly developed, extending from anterior to posterior end, absent only over narrow median field. Testes branched, lateral, in posterior portion of body; cirrus and cirrus pouch wanting genital pore, near posterior margin of acetabulum, either median, right, or left; eggs oval, 0.08–0.1 by 0.05 mm. (Leuckart) or 0.096–0.118 by 0.048–0.055 mm. (Ward) (Fig. 4783).

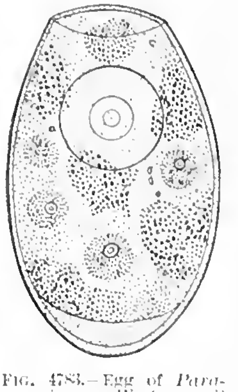

FIG. 4783.—Egg of *Paragonimus Westermanii* (Kerb.). Magnified 500. (After Katsurada.)

The oval ciliated embryo develops within the egg some time after the latter has been discharged with sputum from the host. Further life history unknown.

This parasite has been found in the tiger, cat, dog, and hog as well as in man. It appears from the studies of Ward and Stiles that differences in size are noticeable between the Asiatic (Fig. 4784) and American (Fig. 4782) forms. These differences are noted in the specific description given above. Further study may show them to be distinct species. The different arrangement of the sexual organs may represent the condition of sexual amphitypy noted above.

Distribution.—The parasite is known from Japan, China, Corea, and Formosa, where according to good authorities fifteen per cent. of the entire population is infected. In this country it has been reported from Michigan and Ohio by Ward, and from Kentucky and West Virginia by Stiles, according to whose accounts it seems to be common in hogs of the infested district. Thus far it has not been reported from a human host in the United States. Stiles has made an exhaustive study of the species, but is unable in spite of the recorded differences in size to differentiate specifically the American and Asiatic forms. Even should they prove to be distinct, however, possible danger to man would not be eliminated since the Asiatic form has been found in cat, dog, and hog as well as man, and the American form, which has thus far been reported only from the cat, dog, and hog, may confidently be expected to recur in man in the infected district. Until the announcement by Stiles of the existence of an extensive infection among hogs, it was not clear that the species had actually established itself in the United States, as the two cases in cat and dog which Ward reported might have been introduced from Asia after infection. Now that a large number of cases is known from this country, the endemic character of the species cannot be doubted. It is of the greatest importance that the distribution be more precisely established, and the life history worked out to show the points of danger for the infection of man and the precautions which must be taken to guard against it.

Pathology.—The disease was first reported from man in 1880 by Manson, who called it parasitical hæmoptysis and later endemic hæmoptysis. The term pulmonary distomatosis has also been used. From the cases thus far on record in detail, it is apparently much more prevalent in males than in females, and seventy-five per cent. of these cases occurred among farmers. Both of these facts undoubtedly point to factors in the life history which make infection of such persons easier rather than to any inherent susceptibility; in fact Yamagiwa states that strong persons are more susceptible than weak, but this is evidently because they are more given to outdoor occupations, and hence more open to infection.

Ordinarily the worms are found in the lungs, where they lie in tumors about the roots and along the dorsal border directly under the pleura, sometimes surrounded by a capsule or again burrowing into the lung tissue. The worms occur in man usually one, but in other hosts two, in each cyst, although instances are not rare where one or several have been taken from a cyst, and some cysts contain eggs but no adult worm. The cysts contain not only the worms, but also masses of eggs, and Charcot's crystals, while cholesterin crystals are also occasionally present. The eggs and crystals reach the exterior in masses of mucus and blood through fine openings which communicate with the bronchi. The number of eggs discharged in the course of a single twenty-four hours may be enormous, and was estimated in case of one patient who had suffered thirteen years from the disease as not less than twelve thousand daily.

Yamagiwa has also found in the brain cysts containing the parasites and eggs or simply the eggs. Foci of these eggs and small blood-vessels filled with them occurred in the cortical substance of occipital and parietal lobes; these were associated with giant cells and surrounded by proliferating connective-tissue and round-cell infiltration. The lungs of the same host showed characteristic lesions due to these flukes, so that Yamagiwa concluded that this was the source of the egg emboli found in the brain. These cases, of which several are already on record, are characterized by epileptic attacks (Jacksonian or cortical epilepsy).

Yamagiwa has also found cysts containing the eggs of this species in the liver, causing or associated with cirrhosis of that organ, as well as in the diaphragm, peritoneum, mesentery, and walls of the intestine.

Symptomatology.—When in the lungs, its common abiding place, the distome gives rise to periodic hæmoptysis and chronic cough, with rusty, mucoid expectoration; spitting of blood is common but not constant. The condition of the patient remains good, and almost no abnormal sounds can be detected by percussion of the chest. Yamagiwa says that the general appearance of the expectoration is identical with tuberculosis, and that the disease was formerly diagnosed as such in Japan. The presence in the sputa of the eggs already described makes a positive diagnosis by microscopic examination easy. Accidental rupture of a large blood-vessel by the destruction of lung tissue, and in severe cases general anæmia, are the dangers to be feared.

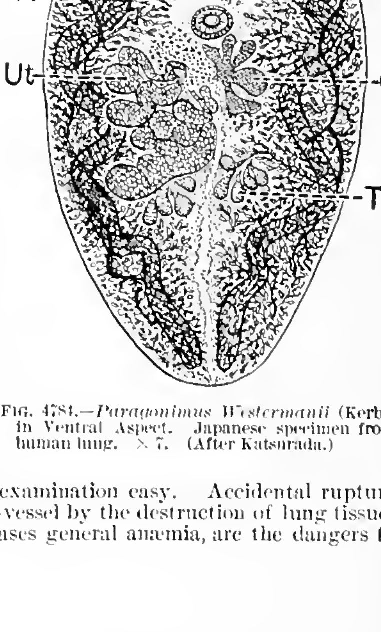

FIG. 4784.—*Paragonimus Westermanii* (Kerb.) in Ventral Aspect. Japanese specimen from human lung. × 7. (After Katsurada.)

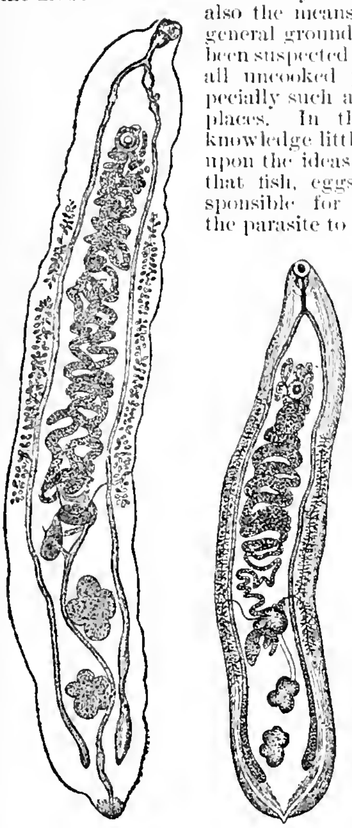
Removal from an infected district is followed usually by complete recovery.

In absence of any knowledge regarding the life history the mode of infection is entirely in the dark, and equally also the means of prevention. On general grounds drinking-water has been suspected; more suspicious are all uncooked plant foods, and especially such as are grown in moist places. In the light of present knowledge little weight can be laid upon the ideas of certain Japanese that fish, eggs, and meat are responsible for the transference of the parasite to the human host.



A. B.

FIG. 4785.—*Opisthorchis felineus* (Riv.). *A*, Elongated Specimen from Liver of Cat. (After Braun.) *B*, "Distomum sibiricum" from liver of man. (From Braun, after Winogradoff.) Magnified.

Opisthorchis R. Blanchard 1895.—Body flat, elongated, broad posteriorly, but tapering toward the anterior end. Cuticula without spines. Testes, lobed or even branching, located one obliquely behind the other in posterior region. Genital pore just in front of acetabulum; no special copulatory organs. Receptaculum seminis large, Laurer's canal present, germarium anterior to testes. Uterine coils anterior to germarium and within intestinal crura. Vitellaria lateral, never anterior to acetabulum. Excretory bladder **Y**-shaped, the long unpaired stem curved like an **S** between the testes.

Opisthorchis felineus (Rivolta 1885.)—(Syn.: *Distoma conus* Gurlt 1831, nec Creplin 1825; *D. lanceolatum* v. Siebold 1836, v. Tright 1889, nec Mehlis 1825; *D. sibiricum* Winogradoff 1892; *D. tenuicolle* Mühling 1896.)

Body much flattened, with sides parallel save that the region anterior to the acetabulum is conical and very changeable in form when alive. Posterior end often slightly pointed. Color faint reddish-brown or yellow; when alive, transparent. Length 8–11 mm., breadth 1.5–2 mm. Suckers separated by only one-fifth to one-sixth of the length, nearly equal in size (0.23–0.25 mm.). Œsophagus very short, intestinal crura reaching nearly to posterior end. Excretory bladder forking anterior to testes. Anterior testis four-lobed, posterior five-lobed. Germarium median, transverse, smaller than the pyriform seminal receptacle just behind it. Uterus entirely within intestinal crura. Vitellaria, in the broad lateral fields, composed of seven to eight distinctly separated groups of follicles, all anterior to ovary. Genital pore immediately preacetabular. Eggs oval with distinct lid at pointed pole, 0.030 by 0.011 mm.

This much confused species has been carefully studied by Braun. It inhabits the gall ducts and gall bladder of the cat, dog, fox, glutton, and man. Of the life history little is known. The eggs when laid contain a ciliated miracidium which, according to Braun, will not hatch out in water, although in Winogradoff's experiments they are said to have done so. Further knowledge on the development is lacking.

Distribution.—Germany, France, Italy, Holland, Scandinavia, Hungary, Russia, Siberia, and if correctly reported Japan also, are the countries in which the species has been found. It is apparently most abundant on the shores of the Baltic, and the general correspondence of its distribution with that of the human tapeworm, *Dibothriocephalus latus*, is worthy of note.

Pathology.—In 1892 Winogradoff found in post-mortems at Tomsk (Siberia) cases of what he thought to be a new human parasite. This he described as *Distoma sibiricum* (Fig. 4785, *B*), but it is probably identical with the species from the cat studied by Braun (Fig. 4785, *A*). Fifteen cases have been reported from Siberia, Russia, and East Prussia. In Tomsk it is the most common human parasite and in East Prussia is also common. Although in no case was a fatal termination attributable to this parasite, yet pathological changes in the liver were noted, such as dilatation of the gall ducts with inflammation and thickening of the walls, and atrophy of hepatic tissue. In recently infected cases the liver was enlarged; in older ones, on the contrary, smaller than normal. Ascites was noted in three cases, icterus in five. Askanazy found hepatic carcinoma in both of the cases he studied closely, and noted that it occurred in the region most visited by the parasites. He was accordingly inclined to place these facts in causal relation since the changes incited by the flukes consisted in manifold, even dendritic, proliferation of the mucosa into the like ise proliferating connective tissue. In both these cases there were over a hundred parasites found in the infected organ, and they were met with also in the pancreatic duct and in the intestine. In other cases on record the number of parasites found varied from a few to several hundred.

In view of the frequent confusion of this species with *Dicrocœlium lanceatum* it is possible that some records included under the latter actually concern the former species. It has been conjectured with good reason that man acquires this species, like *Dibothriocephalus latus*, through the consumption of uncooked fish in which the young distome is encysted, and it is striking that in all of Askanazy's cases in East Prussia both these parasites occurred together. That author, however, was unsuccessful in the effort to infect experimentally with this parasite, or to discover its immature stage.

A closely related American species is one which I originally described as a variety of *O. felineus*, but now believe to be entirely distinct. This is *O. pseudofelineus* Ward 1900 (Fig. 4772), which is a frequent parasite of the cat in some parts of the country, and has been found in the dog and coyote also. The intermediate host is unknown, but many facts point to some fish. Its transfer to the human host might be brought about by chance, or as in the case of the closely related species of the Old World. It occurs here in much the same hosts save man, and consequently would probably be able to maintain itself in the latter host also.

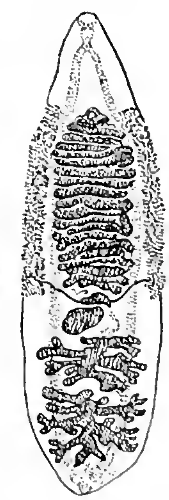


FIG. 4786.—*Opisthorchis sinensis* (Cobb.). Contracted specimen from man in Japan. × 6. (After Katsurada.)

A small spiny distome which Winogradoff found in man in one instance, and which he regarded as the immature form of *O. felineus*, has been tentatively identified by Braun as *Metorchis truncatus* (Rudolphi 1819). This species is a normal parasite of the cat and had probably reached the human host in the same manner as *Opisthorchis felineus*, with which it is moreover often associated in the cat. As this form is parasitic not only in the cat, dog, fox, and glutton, but also in two species of seal, still further evidence is furnished of the transmission of this and the preceding species through fish food.

Opisthorchis sinensis (Cobbold 1875).—(Syn.: *Distoma* *sinense* Cobbold 1875; *D. spathulatum* Leuckhart 1876, nec Rudolphi 1819; *D. hepatis endemicum* s. *perniciosum* Baelz 1883; *D. hepatis innocuum* Baelz 1883; *D. japonicum* R. Blanchard 1886; *D. endemicum* Ijima 1886.) Length 9-15 or even 18 mm.; breadth 2.4-4 mm.*

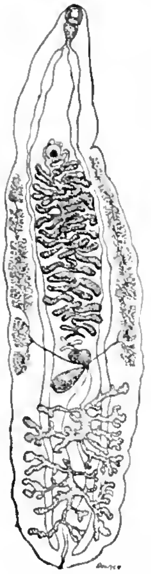

FIG. 4787. *Opisthorchis sinensis* (Cobb.). Moderately extended specimen from man in California. Case of White. Magnified. (Original.)

Body translucent, slightly tinted with yellow or red; form elongate, attenuated toward anterior end, bluntly pointed at posterior (Fig. 4786). Oral sucker larger than ventral and separated from it by one-fourth the entire length. Testes deeply lobed or dendritic, one behind the other in posterior end and overlapping the intestinal crura; anterior to them the prominent receptaculum seminis and then the germarium, faintly lobed, in the median line. Vitellaria lateral, extending from the acetabulum to germarium or slightly further posteriad. Uterus in transverse coils between acetabulum and germarium, but within intestinal crura. Genital pore at anterior margin of acetabulum. Eggs, from fæces 0.027–0.030 mm. long, and 0.015–0.0175 mm. broad; exceptionally 0.035 by 0.019 mm., or at the other extreme 0.02 by 0.0157 mm.; miracidium developed before extrusion from uterus. Parasitic in the cat, dog, and man.

It has been found abundantly in Japan, but occurs also in Corea, Formosa, Tonquin, China, India, and Mauritius. A single case has been reported from New York City by Biggs; the host was a Chinaman. Recently White has found eighteen cases of infection with this parasite (Fig. 4787) in San Francisco. All were detected at necropsies, and of the cases sixteen were pest infected, one had beriberi, and one valvular heart disease. White was inclined to believe that some of the cases were infected in California, though no evidence has yet been published to show that the species has actually established itself on this continent.

In Japan the population is widely infected; the parasite is sporadic in some regions, but in other localities in several provinces it is endemic; in some districts of the province Okayama, according to Katsurada, from fifty-six to sixty-seven per cent. of those subjected to fæcal examination were infected. Of the development the ciliated embryo alone is known. This is formed when the eggs (Fig. 4788) are passed in the fæces of the host; but, according to Ijima, it does not desert the shell spontaneously, even after five months. The intermediate host is probably a mollusk, and the rice fields, which are often fertilized by human excrement, are centres of infection. The mode of transmission can only be conjectured.

The parasite occurs either in the gall ducts and gall bladder or in the pancreatic ducts. It is present also in the duodenum and rarely in the stomach and spleen. The pathological changes are of a mechanical type, and apparently generally proportionate to the duration of the disease and to the number of worms present, which may reach ten thousand or more in a single host. In cases of severe infection the death of the patient follows; this occurs in about fourteen per cent. of the sick. Two hundred and twenty fatal cases were recorded in twelve years in the province of Okayama. Like other species, this parasite has been found outside the liver in pus of a phlegmon on the right side of the abdomen, and in a second case on the diaphragm.

Pathology.—The hepatic lesions produced by flukes were first accurately determined by Schaper for *Fasciola hepatica* in cattle and sheep, and subsequently confirmed by Katsurada and Blanchard, both of whom studied the changes in the human liver produced by *Opisthorchis sinensis*. The results show essential similarity in all cases studied. The lesions are of two sorts; the first, due to the occlusion of the biliary ducts by the parasites, is largely mechanical, and consists in stasis of the bile and dilatation of the ducts with resulting effects on general nutrition. At the same time the resulting inflammation leads to desquamative catarrh accompanied by thickening of the mucosa and glandular hyperplasia. There is also a proliferation of the connective tissue together with increase in blood capillaries and cellular infiltration, which aids in the reduction of liver tissue and in the obliteration of bile ducts. Atrophy of the parenchyma and granular degeneration bring about the destruction of the capillaries, and ultimately the transformation of a larger or smaller portion of the liver into a mass of cicatricial tissue containing only metamorphosed gall ducts.

The effects upon the circulatory system are primarily mechanical in the injuries to capillaries producing multiple hemorrhages, and where these discharge through gall ducts resulting in anæmia. The inflammation produced by the movements of the flukes affects the walls of the blood-vessels and renders it possible for the flukes to gain entrance to the system, and thus be carried to various parts of the body. The growth of connective tissue serves ultimately to compress branches of the portal system, or even partially to obliterate them, and the circulatory stasis is followed by ascites or œdema. Enlargement of the spleen, pathological changes in the pancreas, when that organ also becomes infected, and chronic gastro-intestinal catarrh have been recorded. In fluke disease among animals it has also been noted that the blood is poor in hæmoglobin and subnormal in number of corpuscles.

Opisthorchis noverca Braun 1902.—(Syn.: *Distoma conjunctum* Lewis and Cunningham 1872, McConnell 1876, nec Cobbold 1859.) Body lancet-shaped, spinous, 9.5–12.7 mm. long by 2.5 mm. broad. Suckers close together, the oral being larger than the ventral. Pharynx spherical, intestinal crura extending far posteriad. Genital pore immediately in front of acetabulum; testes round or only slightly lobed, at limit of posterior third of body and nearly opposite. Germarium slightly lobed, in front of bifurcation of the **Y**-shaped excretory reservoir. Uterus in loops through central area from germarium to genital pore. Vitellaria lateral, from testes anteriad nearly to acetabulum. No cirrus sac. Eggs oval, 0.034 by 0.021 mm.

Found in a necropsy in Calcutta in large numbers in the gall ducts of two Mohammedans by McConnell. Similar parasites were discovered a few years earlier by Lewis and Cunningham in the liver of street dogs in the same city. No doubt these forms were both the same species, but Braun has shown clearly that they cannot be the species which Cobbold had found earlier in the liver of an American fox that died in London, and to which the discoverers had assigned them.

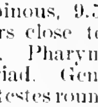

FIG. 4788.—Egg of *Opisthorchis sinensis* (Cobb.) ×500. (After Katsurada.)

Heterophyes Cobbold 1866.—Body without distinct separation into anterior and posterior region. Oral sucker without crown of spines. Pharynx close to oral sucker, intestinal crura extend to posterior end of body. Genital orifice lateral, near acetabulum, surrounded by prominent muscular genital sucker with circle of branched chitinous spines. Vitellaria near posterior margin, scantily developed.

Heterophyes heterophyes (v. Siebold 1852).—(Syn.: *Distomum heterophyes* v. Siebold 1852; *Mesogonimus heterophyes* Railliet 1890; *Cœnogonimus heterophyes* Looss 1900; *Cotylogonimus heterophyes* Lühe 1900.) Length 1–1.7 mm., breadth 0.3–0.6 mm. Limit between anterior mobile and posterior regions often indistinct in alcoholic material (Fig. 4789). Acetabulum very powerful, thick-walled, about

* According to previous reports the worm varies widely in size with hosts and number of individuals present. Even yet it may be questioned whether two or more species are not confused under this name by different observers.

two and one-half times and genital sucker about one and one-half times as large as oral sucker; average diameter of oral sucker 0.09 mm., of ventral sucker 0.23 mm., of genital sucker 0.15 mm. Intestinal crura thin, terminating posteriorly at excretory bladder. Lateral acini of vitellaria outside intestinal crura, sometimes even extending on to ventral surface. Testes near posterior end, just anterior to tips of intestinal crura. Germarium median in posterior region, uterus covering nearly entire posterior end. Eggs light brown, thick-shelled, 0.03 by 0.017 mm.; ciliated miracidium fully developed when egg is deposited (Fig. 4790).

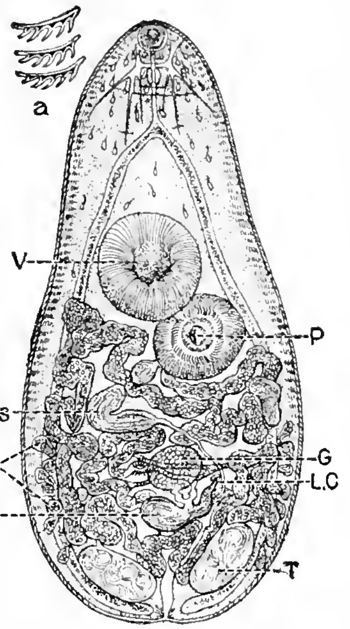

FIG. 4789. — *Heterophyes heterophyes* (v. Sieb.) in Ventral Aspect. *a*, Cuticular spines from margin of genital sucker, *P*. Other letters as before. × 42. (After Looss.)

Parasitic in dog, cat, fox (?), and man in Egypt. A single record of its presence in dogs in Japan needs confirmation. The species was discovered in 1851 by Bilharz in the intestine at the necropsy of a boy in Cairo. The belief that the species was rare in man has been dispelled by the studies of Looss, who finds it rather common; on account of its diminutive size, however, it is easily overlooked. This author has also recently differentiated some closely related species which have been found in other hosts and listed heretofore under the same name. Its seat is the middle third of the duodenum, and it is often found by the hundreds. It usually moves about freely in the chyle, but may remain attached to the wall or concealed in the folds of the mucosa. The parasite feeds on the contents of the intestine, and neither blood corpuscles nor epithelial cells could be found in its alimentary canal. This accounts for its apparently harmless character even when present in large numbers. In spite of the prominent spines on the skin Looss was unable to recognize in any case alterations in the mucosa of the host, which could be attributed to the work or presence of the parasite. According to Looss also the parasite affects particularly the country population and is wanting in those who live in the cities as well as in Europeans.

FIG. 4790.—Egg of *Heterophyes heterophyes*. × 500. (After Looss.)

Dicrocœlium Dujardin.—Body delicate, semitranslucent; form elongate, foliate, tapering toward both ends, with smooth cuticula; oral and ventral suckers separated by less than one-fourth total length. Pharynx small; œsophagus short; intestinal crura long but not extending to posterior end. Cirrus sac anterior to acetabulum, enclosing coiled seminal vesicle and long slender cirrus. Genital pore between pharynx and fork of intestine. Testes compact, forming with the smaller compact germarium a median series directly posterior to acetabulum. Laurer's canal and receptaculum seminis present. Uterus in transverse coils, filling region posterior to germarium. Vitellaria lateral to intestinal crura, only moderately developed. Eggs dark brown, numerous.

Dicrocœlium lanceatum Stiles and Hassall 1896.—(Syn.: *Fasciola lanceolata* Rudolphi 1803, nec Schrank 1790; *Distomum lanceolatum* Mehlis 1825; *Dicrocœlium lanceolatum* Dujardin 1845.) Length 4, usually 8–10 mm., breadth 1.5–2.5 mm. Body flattened, lanceolate, attenuated toward both extremities, especially the anterior (Fig. 4791). Suckers separated by about one-fifth total length; diameter of oral sucker about 0.5 mm., of ventral about 0.6 mm. Intestinal crura terminate one fifth of total length from posterior end. Genital pore at intestinal fork. Testes slightly right and left of median line. Vitellaria from posterior testis through about the middle fifth or fourth of body. Loops of uterus extending laterally beyond intestinal crura. Eggs 0.038–0.045 by 0.022–0.030 mm., thick-shelled, dark brown when deposited, and containing a spherical or oval miracidium ciliated only at anterior end and supplied with rudimentary intestine and boring spine.

Parasitic in gall ducts of herbivorous and omnivorous mammals very generally, often in common with *Fasciola hepatica*. Among the hosts given are sheep, cattle, horse, ass, deer, goat, hare, rabbit, pig, and man. The records in accordance with which this species occurs in dog and cat rest on confusion with *Opisthorchis felineus*.

The development of the species is unknown. Leuckart found that the miracidia spontaneously desert their shells in the intestine of certain slugs (*Arion*, *Limax*), but that no further development could be induced here or in other snails. On the basis of a single feeding experiment, however, he considered small species of *Planorbis* from fresh water to be the larval host. Piana conjectured that land snails were more probably responsible. No further evidence has been obtained.

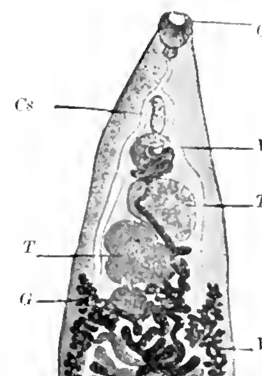

FIG. 4791. — *Dicrocœlium lanceatum* Stiles and Hassall. × 12. (After Braun.)

The distribution of this species is less extended than that of *Fasciola hepatica*, though in general much the same. Leuckart believed it more abundant in southern Europe than in the north. It is wanting in England, but has been recorded among extra-European countries in northern Africa, Siberia, Turkestan, North and South America.

Seven cases of human infection are on record. They come from Germany, Bohemia, Italy, France, and Egypt. With possibly a single exception the parasite was not the cause of any apparent trouble. In view of this absence of dangerous symptoms Braun conjectures that mild infections may be much more frequent than is known.

The family of the Schistosomidæ Looss contains flukes of separate sexes with the male shorter and thicker than the slender female, and having a canal formed by the ventrally turned margins of the body. The acetabulum is stalked and the intestinal crura unite posterior to it. Only one genus is important here.

Schistosoma Weinland 1858.—Female filiform; male very broad with body rolled together ventrad to form completely closed *canalis gynæcophorus*. Suckers near together. No pharynx. Intestinal crura in male join often far back. Genital pore in both sexes median, postacetabular, no copulatory organs. Testes of five to six vesicles. Seminal vesicle small. Uterus of female very long, at times with large numbers of eggs. Eggs tapering equally to both ends with small terminal spine at posterior end, without lid. In venous system of mammals.

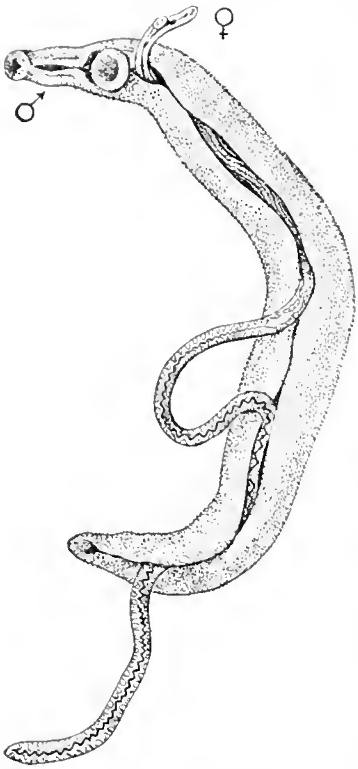

FIG. 4792.—*Schistosoma hæmatobium* (Bilharz). Male and female *in copula* and before the beginning of the production of eggs. × 12. (After Looss.)

Schistosoma hæmatobium (Bilharz 1852).—(Syn.: *Distoma hæmatobium* Bilharz 1852; *Gynæcophorus hæmatobius* Diesing 1858; *Bilharzia hæmatobia* Cobbold 1859; *Thecosoma hæmatobium* Moq.-Tand. 1860; *Bilharzia capensis* Harley 1864.) Male 4, or usually 10–14 mm. long, 1 mm. broad, 0.14–0.17 mm. thick; female 8, or usually 13–20 mm. long, 0.28 mm. broad, 0.21–0.25 mm. thick, oral sucker 0.2 mm. in male, 0.07 mm. in female. Acetabulum pedunculate; diameter 0.28 mm. in male, 0.059 mm. in female. Eggs 0.12–0.19 mm. long, 0.05–0.073 mm. broad, spindle-shaped with median enlargement and with rudimentary filament at posterior end.

Structure.—Through the admirable recent studies of Looss the earlier work of Leuckart and others has been confirmed and extended so that a precise account can now be given of this unique form. The two sexes must be considered separately save that both agree in the delicacy of structure consonant with their existence in the blood current. The male (Fig. 4792) shows papillæ or warts over the entire dorsal surface, except near both ends of the body. Fine dermal spines cover the suckers both within and without. Slightly larger spines cover ventral surface of the body from the genital pore to the posterior tip, *i.e.*, the so-called *canalis gynæcophorus*, as well as form a zone on the dorsal margin of that side which lies within in the formation of the canal. A pharynx is wanting and the œsophagus with two expansions (*A*, *B*, Fig. 4794) covered with a layer of salivary cells terminates at or near the acetabulum, branching to form the intestinal crura. These may join soon to form the unpaired cæcum, which extends in the median line nearly to the posterior end, or their junction may not occur until the posterior fifth of the body is reached; one also finds the crura separating for short intervals in the course of the unpaired cæcum. The food mass in the alimentary canal of the parasite consists chiefly of leucocytes with pigment from the liver and a few erythrocytes.

The reproductive system departs widely from that of other Trematoda described in general above, first in that the sexes are separate, but secondly and equally strikingly in its structure. In the male (Fig. 4794) the testes, four or five in number, lie alternately right and left of the median line not far behind the acetabulum. As the apparent common duct is in reality a part of the organ, the group represents rather a very deeply lobed single testis. The short duct joins this to the sausage-shaped seminal vesicle, from which a short simple canal extends to the sexual pore. This pore is always located exactly at the entrance to the canalis gynæcophorus. Special copulatory organs and glandular adnexa are entirely wanting.

The body of the female is smooth except on the inner surface of the suckers, where extremely fine spines are numerous and the posterior tip of the body, which carries much stronger spines, pointed in various directions. A pharynx is wanting; the œsophagus with dilatations and gland cells, as in the male, divides anterior to the middle of the acetabulum, to form the intestinal crura, which unite behind the germarium to proceed as an unpaired cæcum in a zigzag line, with regularly alternating lateral diverticula to the posterior end.

The female reproductive system (Fig. 4793) lies largely between the acetabulum and the posterior junction of the intestinal crura. Just anterior to this junction one finds the median, elongated oval germarium. The single vitellarium with symmetrical follicles right and left of the intestinal cæcum, occupies the posterior end of the body. Its duct lies parallel to the germ duct coming from the posterior end of the germarium, and joins it at the shell gland, which is located a short distance anterior to the germ gland. After a short ootype the uterus extends nearly directly as a tube of uniform calibre in the median line to the genital pore which lies immediately behind the acetabulum.

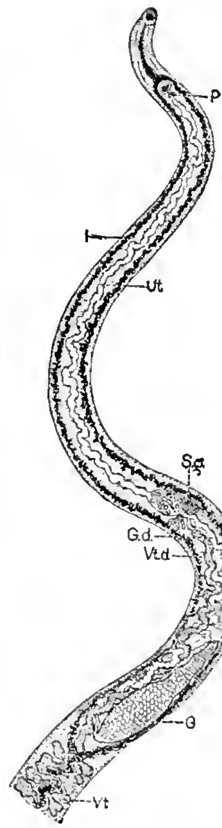

FIG. 4796. *Schistosoma hæmatobium* (Bilharz). Anterior region of female in ventral aspect. The uterus does not contain as yet any developing ova. Letters as before. × 19. (After Looss.)

The egg (Fig. 4795) has the form of a compressed spindle somewhat inflated at the middle. At the posterior pole one finds a short irregular tip, homologous to the filament on the eggs of ectoparasitic trematodes. In those eggs which are discharged in urine this process is terminal, in such as remain in the body of the host it is slightly lateral. The egg shell contains a mature embryo, cylindrical in form with conical anterior tip, or papilla, and covered by a coating of fine cilia. A rudimentary alimenatry canal, cephalic gland, and the usual masses of germ cells in the posterior end are easily distinguishable.

All authorities, save one, agree that the embryos do not hatch out if the eggs are left in unaltered urine, but that the addition of fresh water, especially if warm, brings about at once the opening of the shell and escape of the embryos. If left in urine the embryos die in the shell in from six to twenty-four hours. The further fate of these embryos is entirely unknown, as also the manner of infection. It has been conjectured that the sporocyst stage also occurred in the human host, but the experiments of Looss on apes were without result.

This species occurs as a parasite in the portal system of man, perhaps also in the Sooty monkey and in cattle.

It is widely distributed in Africa, records being at hand of its occurrence in Egypt, along the eastern coast, at Cape of Good Hope, and at points on the western and northern shore as well as in the interior. It is very common among the Egyptian laborers, and boys and youths seem to be particularly susceptible to its attacks. One-third or more of those examined by different observers were found to harbor the parasite. The centre of infection at Mecca (Arabia) is regarded as introduced, and that recently discovered on the island of Cyprus is probably similar.

A case has just been reported by Manson in which the eggs were found in the fæces but not in the urine of an Englishman in the West Indies, who had never been in any country where the parasite is known to exist. On account of its peculiar features the case needs confirmation, but if correct demonstrates the existence of a new centre of infection near our shores.

Stiles says that the human blood fluke has been found twice in this country; once in a foreigner on the "Midway" during the Columbian Exposition and once in New York City. I have found another case recorded from Georgia. All these cases were certainly infected elsewhere, and there is no evidence to show that the parasite has been able to gain a footing as yet in this country.

Pathology.—The females apparently go into the venous plexus of the pelvis to oviposit, and the eggs are carried thence by the blood current into various organs. Here they accumulate, occluding the vessels and causing various symptoms according to the organ affected. Such accumulations have not been found as yet in spleen, stomach, or pancreas. In the lungs they determine lesions which simulate those in miliary tuberculosis, and though rarely recorded as yet are believed to be common. Tumors of similar origin have been rarely met with in mesenteric ganglia, on the peritoneum and in the skin.

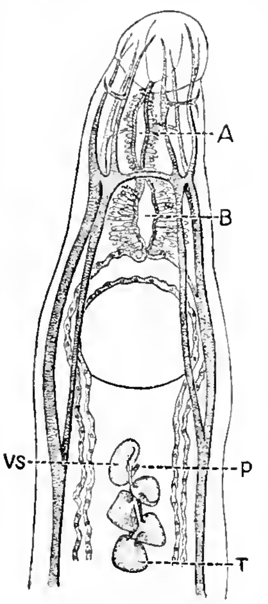

FIG. 4794.—*Schistosoma hæmatobium* (Bilharz). Anterior end of male showing male genital organs and also in part nervous and alimentary systems; *A*, *B*, enlargements of œsophagus with glands; *P*, sexual pore; *T*, testis; *VS*, seminal vesicle. × 48. (After Looss.)

In the liver cirrhosis and biliary calculi are produced by their presence. More frequently one can trace them to the walls of the urinary passages or of the large intestine, and here more serious difficulties arise. Catarrh of the bladder and pain in the lumbar region ensue and are accompanied by the appearance of blood or bits of blood and pus at the close of micturition, which at first occur only occasionally but later regularly. This so-called Egyptian hæmaturia, or bilharziosis as it is called after Bilharz, the discoverer of the parasite, can be definitely diagnosed by the microscopical demonstration of the eggs in the urine. It should be noted, however, that these may be present in the urine without the least trace of blood. The disease may continue for some time, even six to eight years, and eventually terminate without more extended symptoms.

Renewed or reinforced infection, however, intensifies the cystitis and often brings about urethritis as well. Frequently one finds urinary calculi, in many of which the nucleus of the calculus can be shown to consist of one or more fluke eggs. In Egypt one series of observations showed the coincidence of bilharziosis with lithiasis in eighty per cent. of observed cases. In more severe cases the changes may extend to the ureters, kidneys, and colon. The urine contains larger amounts of blood and eggs, and the fæces present a similar appearance. The symptoms then resemble tropical dysentery, and Bilharz, the discoverer of this parasite, originally connected the two in a causal way. As a result of the changes outlined, nutrition suffers and finally death ensues from uræmia, pyæmia, pyelonephritis, or general marasmus. The wall of the bladder shows under these conditions excessive thickening, together with the formation of excrescences, 1–2 cm. in diameter, filled with the eggs of the parasite; the cavity of the organ is diminished materially, and also the elasticity of its wall. Extensive ulcerations are not uncommon, and in connection with the rupture of small vessels determine the characteristic hæmaturia.

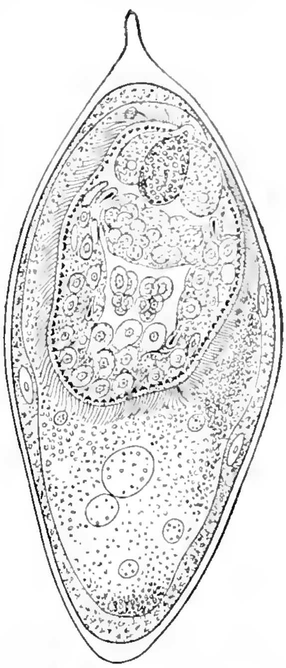

FIG. 4795. — Egg of *Schistosoma hæmatobium* (Bilharz). × 500. (After Looss.)

The disease cannot be regarded as necessarily fatal; its severity depends in general upon the degree of infection. In cases of moderate intensity appropriate treatment of a general character effects a noteworthy amelioration, and in many cases at least the disease is self-terminating. Anthelminthics and other medicaments have been employed with variable results.

Infection is generally attributed to the use of impure water from pools and canals. It has been observed that those villages supplied directly from the Nile are badly infected, while in those using filtered water the parasite is almost unknown. Looss has urged strong reasons in favor of the view that bathing affords the opportunity for the parasite to enter the body through the skin. Both the means of infection and the subsequent course of the parasite in reaching its location in the portal system are, however, entirely conjectural. *Henry B. Ward.*

TRENTHAM SPRING.—Campbell County, Georgia.
POST-OFFICE.—Fairburn.

ACCESS.—Viâ Atlanta and West Point Railroad to Fairburn, thence by private conveyance three miles north to spring.

For a number of years this spring had considerable local reputation. The principal ingredients of the water are as follows: Calcium carbonate, magnesium carbonate, iron carbonate, potassium carbonate, magnesium sulphate, sodium chloride, alumina, organic matter. The waters of this spring are said to be highly efficacious in the treatment of syphilis and scrofula.

James K. Crook.

TREPANNING; TREPHINING.—By common consent these terms are applied, not merely to the application of that form of circular saw known as the *trepan* (or diminutive *trephine*), but to any procedure by which a piece of bone is elevated, or is removed, in order to permit the elevation of some adjoining portion, or the exposure of the membranes or brain beneath. The operation dates back to the remotest antiquity, and seems to have been practised at various times among various peoples as a rite or ceremony. Except when performed by surgeons, it seems to have been done usually with the rudest of implements, and even the instruments used by the previous generation of surgeons were in most respects clumsy and coarse.

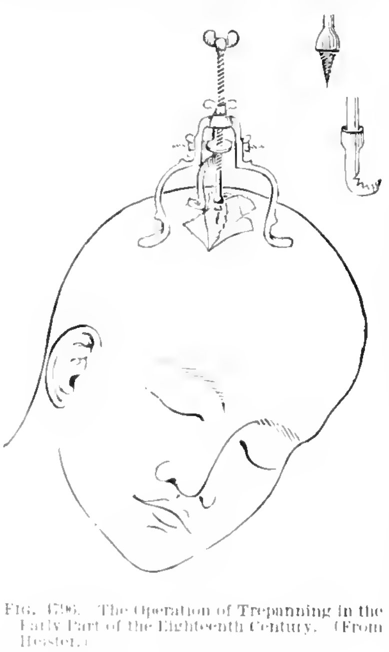

FIG. 4796.—The Operation of Trepanning in the Early Part of the Eighteenth Century. (From Heister.)

INDICATIONS.—1. Simple fractures of the skull, with signs of compression.

2. Compound fractures, with depression, even without signs of compression, except over the frontal sinus, in adults.

3. Punctured and gunshot fractures, even without symptoms. (The reader is referred to the article on *Head, Wounds of*, in Vol. IV. of this HANDBOOK, where I have considered these indications in greater detail.)

4. Coma, with signs of compression, contusion, or laceration of soft parts, without fracture of the external table.

5. Hemorrhage. The operation is done in this case either to tie a vessel or to remove a clot. This is partially included under heading 4.

6. Abscess of brain.

7. Tumor of the brain or meninges.

8. Bone abscess in the frontal sinus, mastoid process, etc.

9. Purulent meningitis, the object here being to wash out the suppurating cavity.

FIG. 4797.—1, A Fractured Skull after the Application of the Trephine and the Removal of the Fragments. (After Charles Bell.) *A*, *B*, The flaps of integument; *C*, the cranium; *D*, the dura mater exposed.

10. Acute infectious osteomyelitis of the diploë.

11. Epilepsy or insanity, when any lesion can be localized with sufficient definiteness.

12. To afford a so-called "relief opening," for relief of pain or cerebral irritability. (See also under *Brain, Surgery of*.)

Each one of the foregoing conditions is an indication for working through and underneath one or both tables of the skull, in order to effect whatever may be possible beneath the level of the bone removed. The various conditions are discussed in their appropriate places; we speak here only of that which pertains to the operation proper.

DANGERS.—The South Sea Islanders scrape through each other's skulls with pieces of glass, we are told, and with impunity. Among the Cornish miners the operation was, up to a comparatively recent date, according to Michel (*American Journal of the Medical Sciences*, October, 1879), one of daily occurrence. The Count of Nassau was trephined by Chadbourn some twenty-seven times. And all this at a time when, or among a people in whom, fear of sepsis has not prevailed. And yet, until very recently, there has been a recognized school of practising surgeons who have uttered solemn warnings against even a properly discriminating resort to the procedure, and fierce wordy battles have been waged concerning it. But the medical profession is now almost a unit in favor of a diagnostic use of the instrument, as it is in favor of an exploratory abdominal section. We are now in a position where one may boldly affirm, even in courts of law, that *trephining is not, by itself, a dangerous operation, when properly done*, but it must be insisted that the *proper* performance of the operation includes the most careful attention to antiseptic or aseptic measures. When these are rigorously carried out the *operation* is no more dangerous than the amputation of a finger with the same precautions. *The condition which*

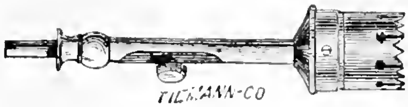

Fig. 4798.—Crown Trephine.

necessitates the operation constitutes the main element of danger. Patients frequently die after trephining, but very seldom because of it. This statement cannot be too strongly emphasized.

Moreover, the operation is frequently too long delayed. Michel's dictum, "The early trephine is gold, the late trephine is lead," should sink deeply into the mind of every one who may ever be compelled to use the instrument. This obtains especially with regard to fractures of the skull. Much better is it to make a puncture and then find it unnecessary to proceed further, than it is to have it appear later that early operation might have saved a life.

The Operation.—Even the instruments and methods of twenty years ago are almost abandoned in favor of those of recent introduction. The Hey's saw and the old bone-cutting forceps are now relegated to the past. The former is never used and the latter are superseded by so-called rongeur forceps, which not only divide the bone, but bite out a small section. They are of various patterns, and can be made extremely useful. Three different methods of operating are now in vogue:—

(*a*) The old-fashioned method, which called for the use of the trepan or trephine, such as is shown in Fig. 4798. When the surgeon's intent is merely to make an opening in the skull through which he may elevate depressed bone, or drain an abscess, this pattern of instrument will still be found useful. It is made in various sizes, but for ordinary work one about 2 cm. in diameter will be found the most serviceable. Small trephines will answer for the introduction and exit of small wire saws, such as those introduced by Gigli and known by his name. These had recently a short vogue, but have been found likely to injure the dura.

(*b*) The mallet and chisel have come into quite general use especially among the continental surgeons. Chisels of various sizes or gouges, variously patterned, will be found in many instances very serviceable, and with them openings of any desired shape and size can be made. The use of the chisel is, however, attended by the theoretical danger of injury from the repeated blows of the hammer, which it has been supposed might cause some molecular disturbance or concussion. Moreover, frequent blows of the hammer may under, certain circumstances, produce a noise which would be distasteful to those within hearing. Still it is not always possible to dispense with these instruments in this kind of work.

(*c*) The osteoplastic method of operating has come into general use since the previous edition of this work. It consists of raising trap door flaps of bone by circular or lateral cuts, which leave a base at that point where the largest vessels enter the scalp, and of springing back this bone flap by breaking it across the base without separating from it the overlying scalp and soft tissues, through which it may still be nourished after its replacement. This method has a very great advantage over any other in that it provides a perfectly adequate bony covering for the bone defect made by the operation, that this covering is of the patient's own tissues and not a foreign body, and that the area thereby exposed can be made of any desired extent in almost any desired location. Thus it has an advantage over all other methods in suitable cases.

This bone flap may be cut out with the chisel, which often takes a long time, by the electric saw or surgical engine, which is an elaborate, e pensive, and unreliable device, or, best of all, by the Stellwagon trephine as improved by Da Costa (Fig. 4802). This is a recent device corresponding very nearly to the carpenter's expansive bit. It contains an arm whose outer extremity carries a small saw, which can be fastened into the axis of the instrument so as to cut in a circle of any desired diameter. The centre pin may be fixed in a small metal plate with sharp point, which may be made to perforate the scalp and penetrate the bone deeply enough to serve as a centre for the rotation of the instrument. With it sections of a circle may be success-

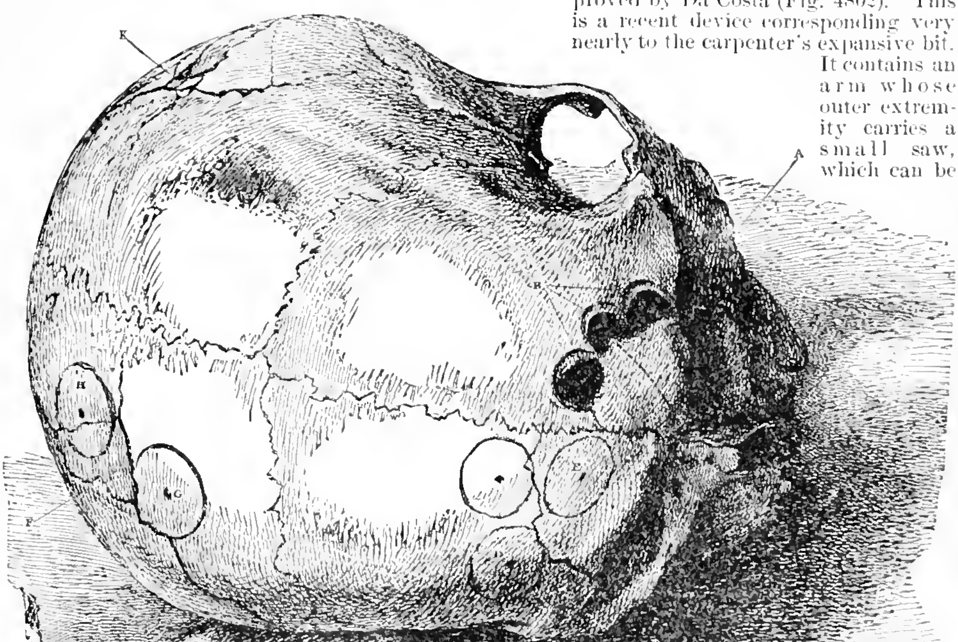

Fig. 4799.—1, A Skull showing Various Examples of Fracture. (After Charles Bell.) *A*, A triangular portion of the os frontis fractured and depressed. *B*, The three perforations found necessary for its elevation and extraction: the second and third were rendered necessary by the fact that the edge of the inner table lay under the sound bone. *D*, A point where the trephine was employed for a fissure of the os frontis represented on its right side; a second perforation was made in the sound bone a little higher up, still the bone could not be extracted; the trephine was then applied at *E* and the bone lifted up. It should have been applied at *E* in the first place. *F*, A fracture with depression at the lower angle; the trephine was placed at *G*; it ought to have been a large one, and placed at *H*, by which a portion of the bone would have been saved and a more favorable form of opening obtained; by perforating at *G* an acute angle of bone was left between *G* and *F*. *K*, A comminuted fracture.

ively cut out from the bone without having to make an opening for the centre pin, and, if it is desired, a small knife may be inserted in place of the saw and made to cut the first circular incision in the scalp. This should be made at a point outside the line where it is proposed to cut the bone, in order that the skin incision shall not exactly overlie that in the bone. If three hundred degrees of a circle be cut with this instrument, it will be easy to snap across the base of the circular bone flap thus made. In this way a veritable trap door may be made to open and afford easy access to the cranial contents beneath.

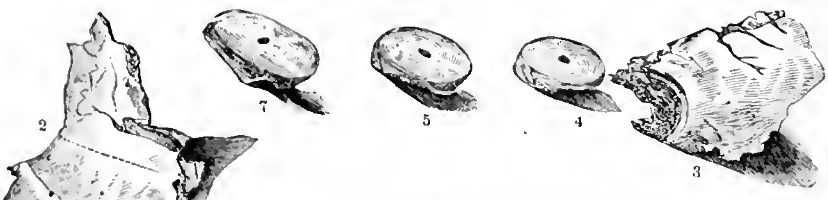

FIG. 4800.—2, The piece of bone removed from *A*, Fig. 4799, with its inner table projecting beyond the outer. 4, The button of bone removed in order to elevate the fragment represented in 3. Here by careless work the surgeon might have pressed on the depressed portion with the trephine, and thus have depressed and chafed the dura. 5 and 7, Buttons of bone having inequalities on their lower surfaces, showing the necessity for extreme caution during the operation. 6, Another button having considerable inner table attached to it, as occurs when the surgeon is obliged to break up the circular portion.

Everything being prepared as for every aseptic operation, the patient's scalp should be carefully shaved and cleansed. If he be in a condition of coma no anæsthetic will be required; if he be restless though unconscious, chloroform should be administered. An existing wound may be utilized, for purposes of exploration at least. If there be no external wound, an incision should be made; and this the writer prefers to make **U**-shaped, in such a way that, as the patient lies on his back, the wound may drain by virtue of gravity from the cut made in raising this **U**-shaped flap. A flap of scalp is thus made over an area as large as may seem indicated. Hemorrhage, which will usually be quite free, must be checked by means of the hæmostatic forceps. Or an Esmarch tourniquet or a thick rubber ring may be passed around or over the cranium. The pericranium is then raised, over a small area, if it be merely for the exploratory use of the trephine, or from the entire area of the depressed bone which is to be removed, if such a measure seem indicated.

If we are dealing with a compound fracture, in which the depressed bone is yet not easily removed, the sole object in trephining is to make an opening through which leverage can be exerted and instruments introduced. Here the ordinary trephine, like that shown in Fig. 4798, may be employed. In order to use it to advantage it must therefore be planted on a rigid and unyielding bony surface. The exigencies of the case can alone make it clear just where this spot may be. Unless it be unavoidable, the trephine should not be applied in the middle line (over the superior longitudinal sinus), nor over the course of any of the large sinuses or vessels, *e.g.*, the middle meningeal. The instrument is provided with a centre pin which is thrust forward a little beyond the level of the teeth so as to secure accurate implantation and prevent sliding. A good way of beginning is to make a little depression—by means of the point of a chisel and a few light blows with the hammer—at the point where one desires to place the centre pin of the trephine. The latter is then applied perpendicularly to the plane of the skull and worked by an alternating motion (pronation and supination of the operator's hand) till its teeth have cut a circular groove. The centre pin is then withdrawn, and the trephine is again applied with the same motion till it has cut through the outer table. Its entrance upon the diploë will be known by the free flow of venous blood. It should now be handled with extra precaution, and a probe or fine-pointed instrument should be frequently passed around the groove to ascertain if the inner table has yet been perforated at any point; if it has, the instrument must be made to bear upon the opposite side of the cut. At last, when a locking of the instrument, combined with a definite but indescribable sensation, makes the operator aware that he has nearly perforated the inner table all around the cut, the instrument may be gently rocked, and thus, by a little leverage, the button of bone is sprung loose and either comes out with the instrument or is left somewhat tilted in its place, attached perhaps by dural adhesions or undivided spicula of bone. A probe or the point of an elevator will now dislodge it.

We have spoken of the diploë; the reader must remember that children and the aged have no such tissue between the two compact outer and inner cranial surfaces; hence he must not look for the sign of its being perforated which has been mentioned above, *i.e.*, free venous oozing, nor for the diminished resistance to the hand, nor the altered character of the detritus thrown up by the saw. Moreover, skulls vary in thickness within wide limits. The skull of the colored race is proverbially thick, yet we find just as thick ones in individuals of the white races. The better rule, then, to follow is to act as if each skull were very thin. As every one should know also, its inner surface is liable to be very irregular; therefore to cut through *every* particle of bone would be to make a serious wound of the dura with the saw teeth.

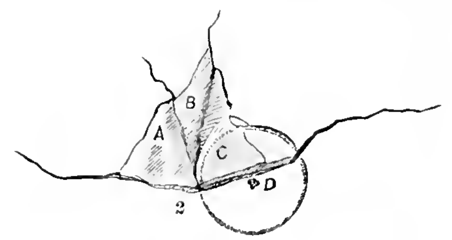

FIG. 4801.—2, Sketch of the Fractured Bone; *A*, *B*, *C*, the three portions of the fractured bone, with depressed edges, which, being sharp, are irritating the dura; they must therefore be removed. They are, moreover, so separated from their attachments as to have lost their vitality. There being no "purchase" for the elevator, the trephine is applied at *D*, and the broken pieces are elevated and picked away. 3, Two discs of bone cut by the trephine, showing the varying thickness of the skull. 4, Exfoliation of bone after use of the trephine. 5, Button removed by the trephine, showing the two tables of the skull with diploë between.

The accompanying illustrations (Figs. 4799, 4800 and

4801) from Charles Bell's "Illustrations of the Great Operations of Surgery" (London, 1821), with their commentary and explanation, will serve to illustrate, much better than can be done by a long description, some of the practical points in the operation. They are also of historical interest since they were drawn by himself.

This is the classical operation with the trephine. With the removal of the disc of bone the first part, at least, of the operation is ended; depressed bone may be elevated, pus or blood evacuated, etc. Still it may be found that *one* such opening is not enough. In this case another suitable position is selected and the manœuvre is repeated, once, twice, or thrice if need be. By means of openings thus made sufficient room may be secured for any further proceeding. Now the rongeur forceps, the Gigli saw, the chisel, or the surgical engine, as the fancy or the equipment of the operator may dictate, may be used to enlarge the openings in any desired direction.

When the opening through the skull has been made for exploratory purposes, or when the contour of the circular aperture has not been disturbed, the disc of bone which was removed, and which may have been kept in a clean, warm, and moist place, may be utilized for the closure of the defect; in other words, a species of osteoplasty may be practised. A little notch is cut, for drainage purposes, on the edge, at what will be its inferior margin when the patient is lying on his back; it is then carefully replaced, the periosteum sutured above it, and over this the scalp, as usual. If the operation has been, as it should be, *aseptic*, this portion of bone should be firmly united with its surroundings in a few days. But if there have been any failure in the precautions such union cannot occur. Those who are unskilled in such technique had better, perhaps, refrain until practice has made them sure.

When the dura mater bulges into the wound, or appears very much discolored, one reasonably infers that it does so because distended by blood or pus within its cavity. In this case it is not only proper but indicated to incise it and explore further. If there be fluid blood it should be allowed to escape, and its source should be looked for. If a clot is found, then it must be gently broken down or dislodged with the probe or irrigating stream and washed away. If pus is present, the dura should be freely incised and its cavity washed out as thoroughly as possible, while subsequent provision must then be made for drainage. We are discussing here the mechanical features of the operation rather than the theoretical and practical applications of the measure, else we should be tempted to enlarge upon the more widespread application of the same to purulent meningitis, whether traumatic or idiopathic.

Bleeding vessels in the dura may be caught with the hæmostatic forceps; if the bleeding be not checked by such forcipressure, a curved needle threaded with catgut may be carefully passed under the vessels and the ligature then tied. So also a wound of a sinus may be treated, only it might be better to use a very fine needle and fine braided silk. When, however, suture of a sinus wall is impracticable, antiseptic gauze may be packed in, or a piece of absolutely aseptic sponge may be used as a compress and allowed to remain without attempting its subsequent removal. Even should a single sinus become obliterated from such treatment, no apprehension need be felt, as Schellmann's researches have shown ("Ueber Verletzung der Hirnsinus"). Injuries to the middle meningeal artery and its large branches are by far the most common of vascular lesions, and when distinct hemiplegia and signs of compression, even without any external signs of fracture, make it probable that this vessel has been ruptured, it is a legitimate and well-recognized operation to trephine over its course, find, and tie it, and remove any clot that may have formed. Parker (*Med. Times*, 1877, i., 91) trephined a case on one side, there being no external lesion, though coma was profound, and found nothing; he then trephined over the artery on the other side, and found no coagulum outside the dura, but since the latter had a distended and bluish appearance, he incised it and removed a considerable amount of blood. In three days the patient became conscious, and then quickly recovered.

The middle meningeal is to be found about one and one-fourth to one and one-half inches back of the external

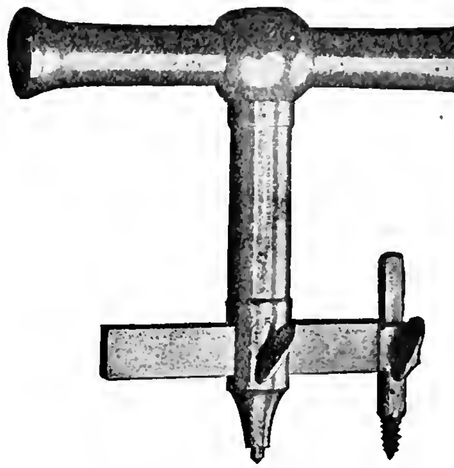

FIG. 4802.—The Stellwagon Trephine.

angle of the orbit. It runs sometimes quite within the bone, sometimes in a groove on its inferior surface, and sometimes quite within or upon the dura.

When one operates for compound fracture every loose piece should be removed. A considerable area of bone, especially in children, is sometimes depressed without being broken loose. In this case it must be raised to its proper level by a combination of dexterity and force properly applied. So much of the periosteum must be saved as is clean and viable. Any portion which has had dirt or foreign material ground into it must be cut away. The scalp will adhere nicely to bare bone, and the periosteum is not necessary, though of advantage, especially over a bony defect.

The medium-sized needle of a good aspirating syringe may be introduced, almost with impunity, to a reasonable depth, in the search for blood, pus, accumulations of fluid in the lateral ventricles, or in testing the density of the brain tissue when hunting for subcortical tumors. It may be used before or after opening the dura. In certain cases its use affords information of great value.

When the brain itself is injured, so that portions of its substance come through the wound, there is not very much to do save to wash away, with extreme care, with a gentle irrigating stream, so much as will easily come away, and then provide for drainage.

All indications having been met, all that remains is to properly close and dress the wound. In a serious compound fracture with deep laceration, the dura should be sutured over the wound in the brain, enough room being left at one point for the introduction of a tent of horsehair, or of catgut, or a decalcified bone or rubber drainage tube, according to the exigencies of the case or the preferences of the operator. If it be so decided, the piece of bone may be replaced and the pericranium united over it in such a way as to hold it in place, provision being made at the same time for a drainage outlet from the deeper parts. The periosteum is best sewed with catgut, and the union should be made as neat and complete as possible. Over this the scalp is united, preferably with catgut; silk or silkworm gut being used only when considerable tension is expected, and with such attention to drainage outlets as the condition beneath demands. A fresh opening or a counter-opening should be made if a more direct outflow may thereby be secured. In an absolutely aseptic exploratory operation there will scarcely arise any occasion for drainage, and it will be enough to omit a suture here and there.

When discharge of pus or any fluid is expected, it is well to provide for it in the dressing. In this case a piece of protective, perforated opposite the drain outlets, may be laid over the wound, and this may be covered with such absorbent material as the operator prefers. But when no discharge is expected and it is desired to leave the dressings undisturbed till healing has occurred, it will be well to cover the wound with one or more thicknesses of gauze, and over this to apply in layers a smooth, equably distributed dressing, with some impermeable stuff outside. At all events, the dressing must be used unsparingly, and it is better to fasten it on with a bandage of starched material. Outside of all a retentive towel, neatly pinned so as snugly to fit the head, will be found very serviceable. Sometimes an ice-bag applied to the head, or an ice-cap, will be found of advantage, especially if oozing be feared. Many surgeons are fond also of administering an active purgative, which certainly is not without value in some cases. *Roswell Park.*

TRI-BENZOYL-GALLIC ACID occurs in odorless and tasteless crystals which are insoluble in water and soluble in alcohol. It is said to set free gallic acid in the intestine, and is employed as an intestinal astringent. Dose 1 gm. (gr. xv.). *W. A. Bastedo.*

TRI-BROM-PHENOL. See *Bromol.*

TRIBROMPHENOL-BISMUTH, Xeroform, $C_6H_2Br_3.O.BiO$, is a fine yellow, almost tasteless powder of slight carbolic odor. It is insoluble in water, alcohol, chloroform, and the oils, but dissolves in two-per-cent. hydrochloric acid. It is unimpaired by heat below 120° C. (248° F.), and so may be sterilized.

Reynders states that in the gastric juice this substance splits into bismuth oxide and tribromphenol. It would seem, therefore, to be a serviceable gastric and intestinal sedative and antiseptic. R. W. Wilcox recommends it especially in the fermentative diarrhoeas, though Brochocki failed to obtain good results in twelve cases of tuberculous enteritis, four of acute gastro-enteritis, three of catarrhal dysentery, and three of typhoid fever. The dose is 1 gm. (gr. xv.) three times a day. It may be found in the urine for twenty-four hours after ingestion, and one of Reynders' patients showed the carbolic reaction with brown urine. In daily doses of 6–7 gm. (gr. xc.–cv.) Hueppe saw no untoward action, and 1 gm. (gr. xv.) administered to a frog, and 8 gm. (ʒ ij.) to a guinea-pig produced no undesirable effect.

The chief use of the remedy, however, is as an external application. There is much clinical evidence showing it to be an antiseptic, deodorizing dusting powder of great value, stimulant to granulation, analgesic, and preventing the formation of pus. It has also been much employed in the treatment of eczema, furuncles, tuberculous ulcerations, chancroids, etc. In ophthalmic work it has been applied as a five- or ten-per-cent. ointment in conjunctivitis, eczema of eyelids, and corneal ulcers; in nasal, pharyngeal, and laryngeal catarrh, and in suppurative otitis media as an insufflation; in gynecological and venereal disease as a local application. There is also on the market a ten-per-cent. xeroform gauze, which has the advantage of being sterilizable by heat. *W. A. Bastedo.*

TRI-BROM-SALOL, Cordol, $C_6H_4.OH.COO.C_6H_2Br_3$, is made by acting on salol with bromine in excess. It occurs in long white needles, which are insoluble in water and slightly soluble in chloroform or glacial acetic acid. It has been proposed as a gastric sedative and intestinal antiseptic in dose of 1–2 gm. (gr. xv.–xxx.), and is said to split in the intestine into salicylic acid and tribrom phenol. The methyl compound of tri-brom-salol, known as "cordeine," and the acetyl compound "cordyl" are also in use. *W. A. Bastedo.*

TRICHINOSIS; TRICHINIASIS. — Although previously observed after death in the muscular tissues of human beings by others, the trichina spiralis was first fully described by Owen in 1835. In 1847 it was discovered by Leidy in the flesh of swine, and in 1849 by Guret in the cat. In 1851–52 Herbst succeeded in developing trichinosis in the dog by feeding the flesh of a trichinous badger. It remained, however, for Zenker, in 1860, to make the first clinical record of a case of trichinosis in man. The disease simulated typhoid fever, but, death resulting, post-mortem examination disclosed the presence of sexually mature parasites in the intestine and of living unencapsulated parasites in the muscles. It was further discovered that others who had partaken of some pork in company with the patient had been made ill, and on investigation this meat was found to contain trichinæ. Subsequent inquiry showed the course of events to be as follows: Human beings become infected through the use of trichinous pork. The capsules of the ingested parasites are digested in the intestine, where sexually mature trichinæ then develop. These begin to give birth to young in the course of a week, and the embryos bore their way through the wall of the intestine into the abdominal cavity, and pass thence by way of the connective tissues to the muscles or to other serous cavities; or they make their way through the mucous and muscular coats of the intestine and between the layers of the mesentery to the vertebral column, whence they migrate to the muscular tissues. In the muscles they penetrate the primitive bundles and cause destruction of the contractile substance. Occasionally the parasites are distributed through the blood stream and the lymph channels. They continue to develop in the muscles for a short time —from two to three weeks—and as a result of their activity febrile symptoms arise, together with others referable to the invaded muscles. In the course of another week the worms curl upon themselves, and in the further progress of the case the irritation to which their presence gives rise causes the formation of a capsule of connective tissue, by which they become surrounded, and which eventually may undergo calcification. The calcified capsule appears as a small grayish nodule, just visible macroscopically. Sometimes the parasites themselves undergo calcification, and occasionally both parasite and capsule disappear entirely. On the other hand, the parasite may retain its vitality for many years and it may even survive the death of its host. It can be destroyed by a temperature of −11° or of 55° C., although greater extremes of temperature are required when the parasite is encapsulated within muscular tissue.

In addition to human beings, trichinæ have been found in rats, mice, cats, foxes, polecats, martens, and raccoons, and trichinosis has by feeding been induced in rabbits, hares, marmots, hedgehogs, moles, sheep, calves, horses, hens, pigeons, and ducks. Dogs are not readily infected. Trichinæ ingested with food remain at times alive for several days in the larvæ of flies. Swine are generally infected through eating the flesh of infected swine fed to them, and occasionally through the flesh of rats infected by eating the refuse from infected porcine cadavers. It is possible also for infection of swine to take place through the ingestion of intestinal discharges from infected human beings or other animals. In man the danger of infection is greatest from the use of raw or imperfectly cooked pork, and it is slightest when the pork is well cooked or roasted. The trichinæ can be destroyed by cooking, provided the temperature in the interior of the meat reaches 75° C. Well-pickled meat is less infective than fresh meat, the trichinæ being destroyed in part by the necessary withdrawal of water. The danger of infection from meat is lessened also by thorough smoking.

Morbid Anatomy.—When opportunity is afforded for post-mortem examination in cases of trichinosis, the mucous membrane of the small intestine is found swollen, in recent cases injected, at a later stage pale. At times there is capillary hyperaemia and there may even be ecchymoses. Swelling of the solitary follicles and of Peyer's patches has been observed, with enlargement of the mesenteric glands. The parasites may persist in the bowel for as long as seven or eight weeks. The spleen is little changed, if at all. The liver becomes pallid and anæmic and of doughy consistence, and its cells the seat of fatty infiltration. The kidney exhibits cloudy swelling or fatty degeneration. The myocardium also may undergo cloudy swelling. The lungs exhibit the signs of bronchitis, with hypostasis, and they may undergo splenization or lobular hepatization. Rarely they are the seat of metastatic abscesses or of hemorrhagic infarction. The muscles may in the first week be light grayish-yellow, dark-red or bluish-violet in color. At a later period the muscle fibres undergo longitudinal and transverse splitting, and degenerative changes take place in the contractile substance, together with hyperplasia of the interstitial connective tissue. Trichinæ may be present in large numbers, especially at the junction of the belly and the tendon of the muscle. They predominate in the diaphragm, the intercostal, the cervical, the laryngeal and the ocular muscles. In the extremities they occur especially in the biceps and the triceps. They have been found also in the heart muscle. Large numbers of polymorphonuclear leucocytes, more especially eosinophile cells, have been described in the affected muscles, particularly in the more degenerated areas.

Symptomatology.—The intensity of the symptoms of trichinosis varies in accordance with the number of parasites introduced into the digestive tract. Three phases of the disease may be considered, namely, that of the entrance of the parasites into the stomach and the small intestine, that of their migration to and through the muscles, and that of encapsulation, with subsidence of the myositis. These are, however, not distinguishable clinically. The ingestion of trichinous meat is followed shortly by symptoms of marked digestive derangement. Among the more common of these are malaise, nausea, eructation, vomiting, and cardialgia, and with them may be associated vertigo, a sense of fulness in the head, and of heaviness in the lower extremities. In some cases the symptoms of an acute gastro-enteritis develop, with diarrhœa, hypogastric pain, weakness, and fever. The diarrhœa may be succeeded by constipation. The appetite is lost, or there may even be repugnance for food. Thirst is increased and sweating may be free. On the other hand, this train of symptoms may be wanting, wholly or in part. The tongue may be dry; it is often swollen and painful, and it may be movable only with great difficulty.

Rheumatoid pains in the extremities develop gradually, with ill-defined feelings of illness. Fever appears, and some of the muscles begin to swell. The affected parts become œdematous and the seat of pain and tenderness. The muscles exhibit weakness and want of elasticity, and there is a sense of soreness such as is observed after unusual exercise. This is noticeable especially in flexion and in the muscles of the neck, and often also in the lumbar muscles. Patients complain further of a sense of heaviness and weight in the extremities.

Febrile symptoms appear, as a rule, on the third or fourth day of the disease, being ushered in by repeated chilliness, rarely by a severe chill. There is slight elevation of temperature in association with the gastro-intestinal symptoms, but the pyrexia becomes more marked with the onset of the symptoms referable to the muscles. The temperature may reach 40° or 41° C. in the afternoon, declining a little in the morning, and being of remittent or subcontinuous type. This higher degree of pyrexia persists for from nine to eleven days, and it is succeeded by a lower range of temperature for a further period of from three to five weeks. In mild cases the temperature may return to the normal level in the third week, or it may become intermittent in character. Defervescence is usually gradual and slow. The pulse frequency corresponds with the degree of pyrexia.

Œdema of the face, especially of the eyelids, appears in the second week of the disease, and is one of the most characteristic and most constant symptoms. There may be an associated chemosis of the conjunctiva. Œdema of the extremities is less common. This symptom, when present, disappears in from two to five days, but it may reappear later.

The trichinæ invade the muscles, and the symptoms referable to these appear at the end of about nine or ten days, though sometimes later, in accordance with the intensity of the infection. The affected muscles become swollen, hard, and sensitive to touch and pressure. Movement induces cutting or boring pain. Such pain as is present is naturally less when the parts are at rest. In mild cases there may be merely a sense of stiffness and of tension. Any muscle of the body may be invaded, but especially those of the extremities and of these particularly the flexors are affected. The patient assumes a characteristic attitude, in consequence of his efforts to relax the involved muscles. In the dorsal decubitus arm, forearm, and hand are flexed at an acute angle, and the lower extremities are partially flexed at the knee and the hip. Stiffness and rigidity are apparent especially in the masseters and the muscles of the neck and the upper extremities. Frequently there is difficulty in deglutition from invasion of the muscles of the tongue and the pharynx, and there may be trismus. Involvement of the muscles of the larynx gives rise to hoarseness and aphonia; of the respiratory muscles, to difficulty in breathing and dyspnœa. Deep inspiration induces dry cough. Œdema of the glottis may develop and give rise to alarming if not dangerous symptoms. In severe cases the ocular muscles may be the seat of pain. This often occurs only on movement, which in consequence is embarrassed. At times the eyes xhibit increased sensitiveness to light, and there may be conjunctivitis and ecchymoses in the scleral conjunctiva. Mydriasis has been observed in some cases.

Pruritus is a frequent symptom, while formication and cutaneous anæsthesia are less common. Eruptions on the skin, such as acne, furunculosis, herpes, petechiæ, prurigo, and urticaria, are not rare as late manifestations. Free desquamation occurs frequently during convalescence. Sweating may be a troublesome feature in both mild and severe cases, and not rarely it continues throughout the course of the disease. Bronchitis is often present early, while in some cases hypostatic and even fibrinous pneumonia develops, and occasionally pleurisy. At times cardiac irritability appears in the second week. Pericarditis also has been observed. In severe and protracted cases venous thrombosis may occur, particularly in the lower extremities, as a result of marantic enfeeblement of the circulation. Rarely epistaxis and intestinal hemorrhage occur, while oligæmia, oligocythæmia, and hydræmia develop early. In the acute stage of the disease the blood exhibits characteristic alterations. The number of leucocytes is increased, at times to a remarkable degree. As many as 35,700 in the cubic millimetre have been reported. This increase involves especially the eosinophile leucocytes, both absolutely and relatively, with coincident diminution in the proportion of polymorphonuclear neutrophile leucocytes. The percentage of eosinophiles has been reported as high as 68.2 per cent., as against the normal of two or three per cent., the percentage of neutrophiles at the same time being 6.6 per cent.

The urine is diminished in amount and is high-colored during the febrile stage, and when sweating is profuse. At a later stage the amount may be increased. Occasionally albuminuria is present, together with tube casts and renal epithelium. Disorders of menstruation are frequent in women, and abortion is not rare when pregnancy exists. Trichinæ have, however, not been found in the fœtus. Insomnia is a constant symptom at the height of the disease, and is invariably present in severe cases. Even in mild cases sleep is disturbed by restlessness. Children, however, may sleep well throughout the disease. The superficial and deep reflexes and the electric irritability to both faradic and galvanic currents are enfeebled. Consciousness is rarely deranged. In some cases impairment of hearing occurs.

The period of incubation of trichinosis—that is, the period of time that elapses between the ingestion of trichinous meat and the development of symptoms—is variable, and may be from a few hours to many days or even weeks. As a rule the first conspicuous symptoms appear during the second or the third week. In mild cases the attack lasts for from one to two weeks. Fever is then likely to be wanting. In severe cases the duration of the attack may be from five to seven weeks to months. The disease not rarely terminates in death. When this occurs it usually does not take place in the first two weeks, but principally between the fourth and the seventh weeks. It is most commonly preceded by symptoms of respiratory paralysis, at times by high fever and typhoid symptoms. Death may be due to complicating pneumonia. The mortality is variable, in different epidemics ranging from none to thirty per cent. In large numbers of cases it averages about five per cent. In children recovery is almost invariable.

Diagnosis.—The diagnosis of trichinosis is based upon the presence of the gastro-intestinal symptoms of the onset of the disease, followed after a varying interval by the development of the symptoms referable to the muscles, with fever, transitory œdema of the face, hoarseness, difficulty in swallowing, profuse sweating, dyspnœa, sleeplessness, and the characteristic changes in the blood, taken in conjunction with the knowledge of a source of infection. In doubtful cases microscopic examination of the stools may disclose the presence of ova or of mature parasites in the stools, or of parasites in a bit of excised muscle, preferably the biceps or the deltoid. Similar examination of any remaining suspected food may yield conclusive evidence of the infection.

If the early gastro-intestinal symptoms of trichinosis are violent they may suggest the existence of cholera; but the characteristic muscular symptoms, the weakness, the sweats, the neuralgic abdominal pains, the changes in the blood, the protracted course, and the absence of the characteristic intestinal discharges, will remove doubt in this connection.

In cases of botulism—poisoning with sausage or meat—the symptoms appear earlier than in cases of trichinosis, and the disease pursues a more rapid course. There is profound depression of the nervous system, with an absence of the peculiar muscular phenomena and of œdema, and the presence of visual derangement, dryness of the throat, slowing of the pulse, icteric discoloration, and dryness of the skin.

The febrile symptoms of trichinosis may suggest typhoid fever, but the presence of the pain and stiffness in the muscles and of œdema of the face, the leucocytosis and the eosinophilia, the results of histologic examination of a bit of muscle, the failure of the blood to cause agglutination and sedimentation of typhoid bacilli in culture, the absence of the diazo-reaction, of rose spots and of enlargement of the spleen will aid in the differentiation.

Mild cases of trichinosis may simulate so-called muscular rheumatism or myalgia from various causes, but the early gastro-intestinal derangement, the puffiness of the face, the respiratory difficulty, and the blood state should be sufficient to prevent error here.

Acute progressive polymyositis is to be differentiated from trichinosis by the absence of gastro-intestinal symptoms and also of the specific etiologic factors, while examination of a bit of muscle will disclose the presence of signs of inflammation, but not of trichinæ.

Prognosis.—The course and termination of an attack of trichinosis depend upon the severity of the infection. When the trichinæ are present in large numbers in the ingested meat, and the method of preparation is inadequate for their destruction, the resulting disease is likely to be severe; while under the reverse conditions the disease is likely to be mild. In general, further, the earlier the appearance of the symptoms the more intense is the infection and the more severe the course of the disease. Persistent and profuse diarrhœa is of evil prognostic omen, as is also initial constipation. The presence of persistent high fever, with slight remissions, of severe and widely distributed muscular pains, of extensive involvement of the respiratory muscles, of intense dyspnœa, of profuse sweats and diarrhœa, of cardiac weakness, of tremor, of delirium and of coma are indicative of an unfavorable prognosis. Want of completeness in the development of the characteristic symptoms, undisturbed sleep, integrity of the respiratory functions and of the circulation after the second week are of favorable prognostic significance. In general the prognosis grows progressively more favorable with the duration of the disease. In mild cases and in children the prognosis is absolutely good.

Prophylaxis.—Human beings can be protected against trichinosis by preventing the spread of the disease in swine. This end can be attained by forbidding the feeding of offal to animals, by systematic and thorough inspection of meat proffered for sale, by prohibition of the sale of trichinous meat, by thorough pickling or smoking, but above all by thorough and prolonged cooking of all meat, and especially of pork, used as food.

Treatment.—Should the patient come under observation soon after the ingestion of the infected meat, emetics or purgatives may be administered, in order so far as possible to expel ova set free in the gastro-intestinal tract. An ounce of castor oil may be employed for this purpose. Anthelmintics have not been found useful, nor have digestive agents proved efficient. Glycerin has been administered in drachm doses every hour for ten or twelve hours consecutively, with the object of abstracting water from the ova, and thus rendering them inert. Benzin has been employed as an anthelmintic, and has been administered internally and also by enema. It may be given by the mouth for several days consecutively in doses of from forty-five to ninety minims in combination with laxatives, and be introduced into the bowel as an addition to an enema through the long rectal tube in doses of from forty-five minims to two drachms. Santonin may be administered in doses of from one-fourth to one grain twice daily, alone or in conjunction with laxatives.

Severe individual symptoms may require special treatment. The initial gastro-intestinal symptoms generally subside spontaneously. In any event remedies that predispose to constipation are strictly to be avoided. To insure thorough evacuation of the bowels laxatives, such as calomel, castor oil, salines, and the like may be administered. For the relief of the muscular pains and stiffness prolonged warm baths may be employed, but they cannot be used if the pain is severe. Inunctions with tepid oil or friction with chloroform or turpentine may afford temporary amelioration. Sleeplessness may be overcome by the use of morphine, but this should be avoided if paralysis of the respiratory muscles is threatened. Hot affusions may aid in inducing sleep. The sleeping-room should, of course, be well ventilated and be kept cool. Sponging with cool water, to which aromatic spirit of ammonia or alcohol is added, also large doses of quinine and the administration of atropine, will prove serviceable in the relief of sleeplessness due to profuse sweating. The application of wet cups to the back will temporarily mitigate the severity of the dyspnœa. Emetics sometimes bring about the same result. In the presence of bronchitis expectorants may be indicated. The diet should be bland, simple, easily digestible, and nutritious.

Augustus A. Eshner.

TRICHLORACETIC ACID.—$C_2HCl_3O_2$. This is one of three chloracetic acids produced by the substitution of chlorine for hydrogen atoms. It is a colorless crystalline salt, deliquescent and freely soluble in water, alcohol, and ether; it has a faint odor and a sharp caustic taste.

This acid is used as a very convenient and delicate test for albumin in the urine. A crystal is to be dropped into the urine, where it rapidly dissolves and produces a cloudiness if albumin is present. A saturated solution may also be used, a few drops being allowed to fall upon the surface of the urine; at the point of contact a cloudiness is at once observed.

This test was proposed by Boymond (*Répert. de Pharm.*, October, 1889), and has been indorsed by numerous observers. The reaction is very prompt and does not require to be confirmed by heat, as peptones are not acted upon. The only danger to be guarded against is the presence of an excessive amount of urates, which will cause a similar cloudiness. This, however, is very slow in appearing and may be overcome by diluting the urine with water.

The chloracetic acid has also been recommended as an escharotic to replace chromic acid. The advantage of this cauterization is that the effects are very localized and do not extend into the surrounding soft tissue. It has been used with success in the treatment of venereal warts, papillomata, and other cutaneous growths. It is used pure, a crystal being placed upon the part, which produces its effect at once. A dry, white, adherent scab forms, which detaches itself after a few days without causing any reaction whatever, and leaving a raw surface which rapidly cicatrizes. A single application may be sufficient for small growths, while for larger ones it may be necessary to repeat the application several times.

These are not very painful, and may be rendered painless by the use of cocaine. Nævi are also reported to have been cured by three or four applications, the cicatrix remaining being very superficial and hardly noticeable. It has also been used successfully in the treatment of chronic inflammations and hypertrophied conditions of the mucous membrane of the nose and throat. In chronic gonorrhœa it has been used by applying it directly to the source of the trouble by the aid of an endoscope.

TRICHOCEPHALUS DISPAR. See *Nematoda.*

TRICHOPHYTOSIS. See *Tineas, The.*

TRICRESOL is a clear, colorless (reddish when older) watery liquid claimed to consist of 35 parts of orthocresol, 40 parts of metacresol, and 25 parts of paracresol. It is soluble in 50 parts of water, and readily in alcohol, ether, and the fatty oils. Major Reed, in a bacteriological investigation, obtained prompt destruction of many pathogenic bacteria by a one-per-cent. solution.

Tricresol was designed as a purified substitute for creolin or lysol, a liquid similar to the latter being prepared by adding 50 parts of tricresol to 35 of soft soap and 15 of water. For use, 4–30 c.c. (ʒ i.–℥ i.) of this mixture is added to one or two litres (quarts) of water. Tricresol has been used for sterilizing instruments, and as a preservative of diphtheria antitoxin. Some of the untoward effects of antitoxin have been attributed to tricresol. De Schweinitz and subsequently Jackson found one part in a thousand an excellent non-irritating preservative of eye washes. McGowan cites a number of cases indicating its efficiency in alopecia areata; other observers have used it much as a vaginal douche; and Vopelius has given it internally in dose of ten to fifteen drops as a substitute for creosote in respiratory troubles. TRIMETHYLAMINE.—$N(CH_3)_3$. Trimethylamine is a tertiary monamine, found native in various plants and also in various animal fluids, notably in *herring-brine*, whose strong, rank odor is due to this ingredient. Prior to the researches on the amines by Hofmann, native trimethylamine was thought to be the isomeric body, *propylamine*, $NH_2(C_3H_7)$, and considerable confusion still exists in medical understanding on the subject, through the misapplication of the term *propylamine* to what is, in truth, *trimethylamine*. As a matter of fact, *propylamine*, properly so called, is not, and never has been, used as a medicine, and all medical preparations passing under that name are preparations of trimethylamine. Trimethylamine is a mobile, colorless liquid of the specific gravity 0.673 at 0° C. (32° F.), and boiling point between 9° and 10° C. (48.2° and 50° F.). It is very soluble in water, which fluid also eagerly absorbs and dissolves the vapor of trimethylamine. It is combustible, and so, too, is its concentrated aqueous solution. Trimethylamine has a powerful and very searching ammoniacal and fishy odor.

For medical purposes an impure solution in water, prepared from herring pickle, was first employed. This solution contained also ammonia and various undetermined ammoniacal compounds, and probably other organic matters. Its proportion of trimethylamine was variable, in accordance with the varying constitution of the samples of herring-pickle of different years' make. Hence, of later years, the definite salt *trimethylamine hydrochloride*, $N(CH_3)_3HCl$, was proposed. This salt occurs in white, very deliquescent crystals, freely soluble in water, and is the best form of trimethylamine for medical administration.

Trimethylamine is a powerful irritant, its concentrated solution being even mildly caustic. Taken internally, large doses—such as in excess of 2.00 gm. (about thirty grains)—produce decided symptoms of gastro intestinal irritation with burning in the throat and stomach. After absorption the medicine evinces a tendency to depress the force and frequency of the pulse, the body temperature, and the excretion of urea.

Trimethylamine was at one time used for the treatment of rheumatism and gout, but of late years has been so completely superseded by the salicylates as to have become obsolete as a medicine. If used at all, the drug is best administered in the form of an aqueous solution of the hydrochloride, aromatized to cover the rank, fishy taste. The dose of hydrochloride will range between 0.25 and 0.50 gm. (between four and eight grains, about), several times a day.

Edward Curtis.

TRIONAL and **TETRONAL.**—These two hypnotics are closely allied to sulphonal, being formed by substituting ethyl groups for those of methyl. In sulphonal there are two ethyl and two methyl groups; in trional an additional ethyl group replaces a methyl group; and in tetronal the two methyl groups are replaced by two of ethyl. The following formulæ explain the differences in their construction:

Sulphonal, $(CH_3)_2C(SO_2C_2H_5)_2$; trional, $C_2H_5CH_3C(SO_2C_2H_5)_2$; tetronal, $(C_2H_5)_2C(SO_2C_2H_5)_2$.

They are the result of a series of experiments for the purpose of determining upon which of the radicals the therapeutic action of the several sulphones depended (*British Medical Journal*, January 11th, 1890). The sulphur-containing radicals were generally supposed to be the active element, but it was found that these had little influence, while the various compounds were more or less active, according as they contained a greater or smaller number of the ethyl groups. Sulphonal with two ethyl groups possessed a certain hypnotic action; when the number was increased its therapeutic power became greater, and when fewer groups were introduced it became correspondingly less. To the compounds containing three and four groups, respectively, the names trional and tetronal were given, the title indicating the number of groups present. They both form in lustrous, tabular crystals; soluble in alcohol, but only slightly so in water—trional to the extent of one part in three hundred and twenty; tetronal, one in four hundred and fifty. The taste of both is bitter, somewhat resembling camphor.

Trional has proved to be an excellent hypnotic, and it is now employed almost to as great an extent as sulphonal. Tetronal, on the other hand, has fallen into disuse. It has proved less manageable and ill effects after its employment are very frequent.

The action of trional is the same as that of sulphonal but more rapid and certain. It acts in from fifteen minutes to half an hour. There is not the delayed action, nor the prolonged sleep that frequently accompanies the effect of sulphonal. It, however, more frequently gives rise to toxic symptoms. These are the same as are caused by sulphonal: lassitude, giddiness, ataxic symptoms, nausea, irritation of the kidneys, diminished secretion of urine, with discoloration due to *hæmatoporphyrinuria*. Cases of prolonged peripheral neuritis have also been reported to have followed its administration. No deaths have been reported from single doses, but many fatalities have followed its prolonged use. A cumulative effect has been noted, which is observed when chronic constipation is marked. A peculiar camphoraceous odor of the urine is an early sign of its toxic action.

The dose is from ten to twenty grains, in hot milk, at bedtime. It has recently been shown that when given in water charged with carbonic acid gas, its action is much more marked, and that ten grains will produce its full effect. Seltzer water is selected for that purpose.

TRIOXYMETHYLENE. See *Paraform.*

TRIPHENETOL GUANIDINE HYDROCHLORIDE is a local anæsthetic used in eye treatment in 0.1-per-cent. solution. Anæsthesia is prompt and the pupil is not dilated.

W. A. Bastedo.

TRIPHENIN, $C_6H_4.C_2H_5O.NH.CH_3CH_2CO$, obtained by heating paraphenetidin with propionic acid, differs from phenacetin only in the substitution of the propionyl radical for the acetic. It occurs as an odorless, white, crystalline powder of feebly bitter taste, and is soluble in two thousand parts of water. It is antipyretic and analgesic, its action being practically that of phenacetin. Dose 0.3–0.7 gm. (gr. v.–x.).

W. A. Bastedo.

TRITICUM. See *Dog-grass.*

TROPACOCAINE HYDROCHLORIDE, $C_8H_{14}.NO.C_7H_5O.HCl$, is benzoyl-pseudotropeine, a principle at first isolated from a Java coca leaf, but now prepared synthetically from atropine or hyoscyamine. It forms colorless crystals which are readily soluble in water and have strongly alkaloidal properties. Resembling cocaine in its physiological effects, tropacocaine is said by Vamossy to be much less toxic and more rapid in its local action, and to cause none of the ischaemia, hyperæmia, and irritation of cocaine. It is employed in solution of one half to ten per cent. in the same manner as cocaine, but its use is confined to that of an anæsthetic.

In spinal anæsthesia, K. Schwarz, who employed it in one hundred cases, reports better results than with cocaine; but two of the cases had vomiting and eleven headache, and there was more or less pallor, cyanosis, slow pulse or fever. Neugebauer, McLean of Detroit, Willy Meyer, and Fowler prefer it in spinal analgesia, while Bier thinks cocaine superior. For use in the eye Vamossy recommends ℞ Tropacocaine 0.3 gm. (gr. v.), sodium chloride 0.06 gm. (gr. i.), and distilled water 10 c.c. (ʒ iiss.), a solution which is non-irritating and strongly anæsthetic, and has little, if any, mydriatic action. Veasey considers the drug especially valuable in keratitis, as it does not deplete the corneal blood-vessels. Its action seems to be very rapid; Silex was able to perform a painless tenotomy one minute after the application of a three-per-cent. solution. Hugenschmidt injected 0.04 gm. (gr. ⅗) in his own lower jaw region, and in three minutes he became dizzy, felt precordial anxiety, and exhibited a marked lowering of blood pressure. Ten minutes after the injection the effect had passed away. In dental surgery Pinet and others recommend it highly, either as a hypodermic injection or in ten-per-cent. solution locally applied.

W. A. Bastedo.

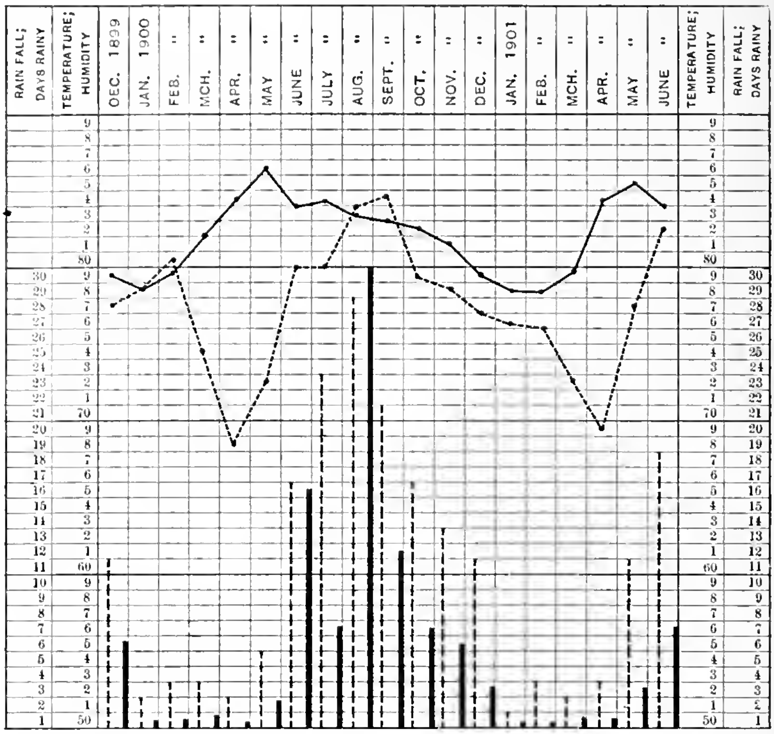

FIG. 4803.—Description of Chart. Each horizontal line represents one degree of temperature and humidity; one rainy day and one inch of rainfall; each perpendicular line, one month; continuous heavy curve, average mean monthly temperature; light broken curve, average mean monthly humidity; heavy black lines in right side of monthly columns, rainfall in inches per month; heavy broken lines near centre of monthly columns, number of rainy days per month; inside column of figures marks degrees of temperature and humidity; and outside figures, number of inches of rainfall and rainy days per month.

TROPICAL DISEASES: GENERAL INTRODUCTION. —Those who desire to acquire a satisfactory knowledge of "tropical diseases," as they are encountered in some special part of the world, must first acquaint themselves to some extent with the surface configuration of the country which is under consideration, with its climatic characteristics, its fauna and flora, and with its people, and then they must study the pathologic aspects of the diseases themselves.

Climate.—To present more clearly the essential features of climate, chart Fig. 4803 has been constructed from data collected in Manila, P. I. Although it is based upon the climatic phenomena observed at only one place in the Philippines, it will serve for most tropical localities, except those situated far inland, where the rainfall may be greatly diminished and where intense hot winds prevail instead of the more pleasant sea breezes.

An analysis of the curves for temperature and humidity shows that these curves cross the 80° (and 80 per cent.) line in February, June, October, and December, thus permitting a more or less arbitrary division of the tropical year into seasons. It will be observed that during December, January, and February, the temperature and humidity are below 80° and 80 per cent.; that during December and a part of January there are a relatively large number of rainy days, but relatively little rainfall; that, as the season progresses, the number of rainy days and the number of inches of rainfall gradually diminish until February, when almost no rain falls. These months are the coldest of the year, and constitute what may be termed the winter season. During the winter the early morning, the late afternoon, and the nights are cool, often cold, on account of the cool monsoons from the north. On the other hand, the middle portion of the day is warm, with blue skies dotted with numerous white clouds. In other words, the days at this season, which is by far the most pleasant of the year, resemble those of our early autumns.

About the first of March the temperature gradually rises above 80° F., each day being just a little hotter than the preceding. In April and May the highest temperature is noted. As the temperature rises humidity sinks to its lowest point in April and May, when the increased rainfall produces a gradual rise to 80 per cent., about the first of June. This is the hot, dry season which continues from the rise of temperature above 80° in March to the rise of humidity above 80 per cent. in June. During this season the temperature is regularly high; humidity low; monsoons frequently absent and often hot, and the skies more or less dotted with white clouds. This is the most unpleasant season of the year. To recapitulate, the hot, dry season continues from early March to June; the temperature is regular and high; humidity low; rainfall almost nil; monsoons often absent and often hot.

In June the number of rainy days and the number of inches of rainfall show a decided increase; in some regions the rainy season may be ushered in by a typhoon. This season continues from the rise of humidity above 80 per cent. in June, to the fall of temperature below 80° F. in November. During the early months, the temperature is a few degrees lower and more irregular than in the hot, dry season. Often during a typhoon relatively low temperatures (62° to 70° F.) are noted. In the last months of the rainy season the temperature gradually sinks below 80° F., when the season merges into winter. The humidity is high; during a typhoon the atmosphere is saturated. These typhoons occur from June to October. They are circular wind and rain storms, the centre of which slowly moves along a fairly well-defined path from southwest to northeast. The nearer the centre is approached, the severer the storm becomes. Destructive winds are frequent during these storms, and the rainfall is often extraordinary; as much as sixteen inches of water having fallen in one day. In the absence of typhoons light showers occur daily. Often every day is rainy. To recapitulate, the rainy season continues from June to November; the temperature is high and irregular; the humidity is high and the rainfall is great; typhoons may occur during this period. The change from one season to another is very gradual.

Throughout the year, monsoons materially diminish the discomforts of a tropical climate. They are winds, the direction of which depends on the location of the centres of high and low pressures. During the summer months the prevailing direction of the wind is toward the north —*i.e.*, toward the northern low-pressure centres. Coming from the equator, these monsoons are warm, often hot. On account of the northern high-pressure centres, winter monsoons have a southerly direction (*i.e.*, they blow from the north) and are cool. Monsoons naturally influence the climate.

In addition to the regular monsoons there are, along the coast, local land and sea breezes which serve to moderate a tropical temperature. These breezes are produced by the difference between the land and the waters as regards the radiation of heat. As heat radiates more rapidly from land, there are, in the late afternoon and during the evening, light winds from the water, whereas in the early morning light breezes blow from inland. These breezes may slightly change the direction of monsoons.

The range in temperature between the hottest and coldest seasons is only eight or nine degrees. This change, with that in humidity and in the monsoons, produces an effect which is felt by the individual in a more decided manner than is shown by the thermometer. The chief features, then, of a tropical climate are a hot, dry season, a rainy season, and a winter season, with a constantly high temperature in each. The latter is the most important feature and more accurately defines the word "tropical" in the expression "tropical diseases" than does the mere geographical signification of the term. In this sense a portion of the year in temperate climates is tropical, and the duration of this tropical period gradually increases as the distance from the equator diminishes, until the Tropic of Cancer and Tropic of Capricorn are reached. Within these parallels the entire year is tropical.

The term "tropical diseases," if used in its strictly geographical sense, includes only a few unimportant diseases; while in the broader sense (which has been given to it in the preceding paragraph) it may properly be said to include the following classes of diseases: First, a small group of unimportant diseases occurring only in the tropics. (Type: yaws.) Secc d, a larger group of diseases which occur in the tropics and subtropics, and occasionally during the hot months in temperate climates. (Type: yellow fever; dengue.) Third, a group of diseases which occur in all climates, but more persistently in the tropics and subtropics. (Type: malaria.) Fourth, a group of diseases which arise in tropical and subtropical regions—in which they are endemic—and at varying intervals of time spread to different parts of the world. (Type: bubonic plague and cholera.)

In addition to the above-mentioned classes, many diseases common to temperate climates are present in the tropics, but to include them in "tropical diseases" would necessitate a discussion of the entire realm of medicine. Diseases which are produced by factors that constitute an integral part of certain meteorological conditions are very few and, as a rule, unimportant. Except in rare instances, they may be prevented. Here may be mentioned frost-bite, sun-stroke, heat-exhaustion, etc.

Indirectly, climate plays an important rôle in all the diseases that are caused by specific agents, the viability, reproduction, pathogenicity and dissemination of which may be greatly influenced by cold, heat, drought, rain, etc.

The Surface Features of the Country.—The topography of tropical countries is essentially the same as that of countries belonging to higher latitudes. In some districts, by reason of their high elevation, several distinct climates may occur within a remarkably limited area. Woodland, often with heavy undergrowth, is abundant. This feature materially aids the long and severe rainy season to supply numerous small streams which often overflow the lowlands. The soil, which in general is very fertile, plays little or no part in the problem of tropical diseases.

The Character and Condition of the People.—Ignorance and poverty are the prevailing conditions in most of the tropical races. At the same time they are, as a rule, very prolific.

History gives us very little information in regard to the rise and progress of these nations. Most of them were found in a barbarous or semibarbarous state; consequently they fell an easy prey to any or all who had time or inclination to mix in their affairs. Generally speaking, their education has been little advanced. In many of the larger cities schools, colleges, etc., and in some country districts a few schools may be seen, but the type of these seats of learning has not been all that might be desired, and at best only a limited number could be benefited. Religions of various kinds have, too often, gained dangerous power; have handicapped their schools and virtually blocked their education and advancement. Their reading has been limited, travelling has been confined to local districts, and most new-comers have adopted local customs. For these reasons their customs, ideas, etc., have remained unchanged from one generation to another. Of modern ideas, they have no knowledge, especially regarding medical matters; their dogmatic religious beliefs are opposed to advancement, and the disregard shown toward their religions, traditions, etc., by civilized man foster, too often, a spirit antagonistic to modern learning.

Poverty and multitudes go hand-in-hand with ignorance to produce the most horrible conditions. The houses of the ordinary natives are poorly planned and constructed; light and sewerage are bad, and their streets are faulty and filthy. These defects become the more manifest in the presence of multitudes, when there is a rapid accumulation of filth, the decomposition of which is most repulsive and to foreigners often sickening. Their houses are crowded, often two hundred and fifty human beings finding lodgment in a single house not larger than an eight or ten-room residence. Their food is poor in quality and insufficient in quantity. Their water supply is usually obtained from small streams, surface wells, and pools. Their sewerage is deposited on the surface of the ground about their houses and yards. In habits they are lazy and little influenced by civil law save when coerced. Thus they fall an easy prey to all contagious, infectious, and parasitic diseases, unprepared as they are to combat infection, to seek the world's knowledge or to profit by the experience of other nations. Naturally, under these conditions epidemic diseases are always present, and it is often difficult to determine the extent of these epidemics.

In the tropics, the physical condition of the people is fairly good. In spite of the fevers, anæmias, etc., many aged people are present to demonstrate the facts that the tropics, *per se*, are not inconsistent with long life, and that the normal conditions of man in a warm climate are almost the same as they are in a cold one. The normal temperature, pulse and respiratory rates, digestion and other functions are about the same as in the higher latitudes. Again, the death rate in the larger cities is not materially larger than it is in other climates, except during an extensive epidemic.

Natives in all climates adopt those customs which are best suited to the local conditions. In the tropics, the houses consist mainly of a roof, floor and walls of such a character as will best keep out the intense light, the severe winds, and the copious rains, and will admit, during ordinary weather, as much air as possible. Their clothing is light. They work during early morning and late afternoon, leaving the middle of the day for lounging and napping. Their lack of mental activity is due more to their origin and ignorance than to a direct influence of climate.

In the tropics the heat-regulating apparatus is not so severely tried as in a temperate or cold climate. But when individuals from other climates enter the tropics the activity of their regulating apparatus must be of another kind. In place of the rapidly changing temperatures, the apparatus must adapt itself to a constantly high temperature. This change in activity is not a serious one, but when associated with changes in food, drink, exercise, etc., it may cause more or less disturbance in the general physiological activity, which may last a longer or shorter time, and may to a greater or less degree reduce the natural resistance of individuals to infection. But when this period is passed, no marked inconvenience from the heat should be felt, as the heat-regulating apparatus is sufficient to compensate the external temperature. When the meteorological observations are considered, it is found that only on rare occasions is the weather as hot in the tropics as it is during the summer months in a temperate climate. If harm does follow it is due more to the constancy than to the degree of heat.

Those who go to the tropics must be exposed to the same infections as are the natives—no more, possibly less, on account of their better hygienic surroundings. Consequently a certain percentage of new-comers will be ill for a certain length of time during their stay in a tropical climate; but if the opportunities for infection are the same as they are in other climates, there is no reason why new-comers should be ill oftener in the tropics than in their former homes. In support of this statement we may be permitted to cite the large number of old natives and foreigners who maintain good health in the tropics, the recent extensive movements of troops in the tropics without injurious consequences, and the specific causes of diseases. Usually, if an individual, shortly after entering the tropics, succumbs, some well-known cause for his death may be looked for.

Statistics of military operations possess practically no value in an inquiry of this nature, for troops campaigning in any country are most liable to diseases.

Fauna.—The fauna of the tropics, on account of an abundance of food, shelter and continuous warm weather, is more diversified than in other climates. The importance of this kingdom in medicine has only recently become prominent by the discovery of the rôle acted by mosquitoes in filariasis, malaria, and yellow fever; by flies, ants, etc., in some of the infectious diseases; and by rats, hogs, etc., in certain infectious and parasitic diseases. These discoveries have demonstrated our limited knowledge of the life-history, customs, anatomy, pathology, and ultimate fate of the several members of this kingdom; and they suggest the necessity for a more systematic study than has heretofore been made. The present importance of this subject, in anticipation of future discoveries relating to the propagation and transmission of disease, should give a new impetus to zoology and entomology. As a matter of course, scientific work along this line is important, but when we add to this the practical knowledge which is to be gained in regard to the dissemination and prophylaxis of diseases affecting man, the importance of this whole subject is greatly enhanced. To medical men, especially those working in pathology, the importance of a thorough training in zoology and entomology is manifest; in fact, there has been opened a new field which in time must yield the solution of many of our perplexing problems.

Recent work on yellow fever demonstrates how this disease depends on the life-history of the Stegomyia fasciata. This species of mosquito is tropical, but can thrive in temperate climates during warm months, to be killed by the first frosts. Yellow fever, therefore, is a tropical disease which often prevails in temperate climates during summer months, to disappear after the first few frosts. Dengue fever probably depends on similar modes of transmission. Future developments in this field cannot now be prophesied.

Flora.—In a general way, what has been said of the fauna applies also to the flora. Besides poisons of plants affecting our races, enzymes may play an important and at present an almost unknown rôle in medicine. Recent work demonstrates the importance of enzymes in plant pathology. May not some of these produce disease in the human being? Some have believed that beri-beri is caused by an enzyme. Whether this be a fact or not, it is plain that there is still abundant room for speculation in regard to numerous diseases of which, as yet, we do not know the causes.

Pathological Considerations.—As pathology and bacteriology have in recent years greatly extended the realm of medicine and have explained many of the formerly obscure points in the etiology, course, treatment, and prophylaxis of diseases, one must turn to these branches for more complete information in regard to "tropical diseases." As our knowledge advances, the rôle of specific organisms as etiological factors becomes greater and greater. The number of diseases now believed to be entirely due to the presence of a specific organism is large and increasing. In this way the group of infectious and contagious diseases has become the most important in medicine.

After the discovery of specific pathogenic organisms, it was found that these organisms usually exist as saprophytes outside of the body, or pass a portion of their life-cycle in some lower animal. These facts expose pathogenic organisms to the struggle for existence and make them, to a great extent, dependent on conditions existing in the several localities or climates.

For saprophytes, a certain amount of warmth, light, moisture, food, and transportation is necessary for their preservation, propagation, and dissemination. Experimentation has shown that many conditions influence the life, reproductive powers, preservation of virulence, etc., of micro-organisms. Consequently conditions present in the tropics may prove unfavorable to organisms which are able to weather temperate or cold climates, and vice versa; it is also possible for an organism to thrive in any climate; and, finally an organism may be so slightly influenced by climatic conditions that for a time it may thrive in almost any locality, only to die out after a longer or shorter period.

Pathogenic organisms, which pass a portion of their life-cycle as parasites in some host of a lower order than man, must depend on the presence of the host, the natural habitat and migrations of which must determine the geographical distribution of the disease produced by the respective parasite. Consequently if the host is tropical or subtropical, or if it has the power to migrate during warm months into temperate climates, the distribution of the disease is in the one case tropical and subtropical, or, in the other, may be present in temperate climates during the summer time. In all cases the fate of the host determines in great measure the fate of the parasite. Pathogenic organisms, which pass a portion of their life-cycle as saprophytes and a portion as parasites, are naturally subjected to all the injurious conditions and fate of the host above noted. On these conditions depend the differences which are observed in certain diseases according as they are encountered in the tropics or in other climates.

Diseases common to temperate and tropical climates may differ in severity, course, etc., even as they do in any given locality; but, as a rule, the clinical course and termination are essentially the same in the two climates. The field of medicine in the tropics has not been so thoroughly worked as it has been in many places; hence there are doubtless many unrecognized diseases which serve to complicate the picture of some common affections. This possible and unavoidable error in diagnosis should encourage the medical man, in the presence of a disease which simulates malaria or typhoid fever, etc., but in which the clinical diagnosis is not confirmed by laboratory methods, boldly to announce the diagnosis as undetermined. In this way the attention of pathologists could more easily be directed to undetermined diseases.

Certain organisms thrive luxuriantly outside of the body and produce toxins, which may, independently of the presence of these organisms, cause disease. This condition is called intoxication. Ergotism and pellagra belong to this class. Owing to the favorable conditions in the tropics for the growth of these parasites, their toxins may play a more important rôle than is at present recognized.

In no climate are the conditions so favorable to parasitic diseases as in the tropics. The dress of the natives and their peculiar customs favor parasitic skin diseases, and, as a matter of fact, these are very common. Intestinal parasites are rife and filariasis is quite a common disease.

Of the diseases which affect both man and animals, cysticercus, glanders, and anthrax, etc., are most important. They naturally vary in frequency in the several districts. In Manila about four per cent. of the hogs killed are infected with cysticercus; only a few with trichinæ. Yet the cases of these diseases in man are comparatively rare. In about two hundred autopsies only one instance of tænia was found; clinically, only a few cases were noted. Glanders is prevalent in some districts, but the disease in man is rarely noted. Anthrax is also rare.

Diseases among animals are rife; epidemics of cattle plague, etc., are frequent.

General Remarks.—While ordinarily the climate is equable, during the rainy and cold seasons sudden changes often occur which have a more pronounced effect on natives than on foreigners. During these times the natives wear their heaviest clothes, yet seem to be cold and uncomfortable. This condition is often intensified by the severe rainfall and high winds accompanying typhoons, at which times all note the marked increase in the amount of urine secreted, this increase being caused by the inactivity of the skin. The fact that an increase in the number of small cells has been observed in sections of kidneys removed at autopsy from cadavers of various ages has furnished ground for the belief that these organs were in a more or less irritated state, and that this irritation was probably due to a diminution in the excretion of urine, dependent upon the general increase in activity of the skin.

During ordinary weather the natives wear very few clothes, are barefooted, and thus are exposed to infection of various kinds. Living, as they do, crowded together in small rooms, usually on the floor, infection rapidly spreads. It is astonishing to see a native well dressed and apparently clean living in the filthiest surroundings. These people seem to like it. Often their food is kept, cooked, and eaten amidst filth. Their domestic animals, cows, hogs, goats, chickens, etc., have free access to the house, and often convert the premises about the home into a pen. In larger residences, in many places, the stable occupies a portion of the house. Night-soil is usually kept in pails in the house, to be carried off by tenders to garden patches. The water supply of the natives is often derived from pools and small streams which are unprotected and which flow through fields on which night-soil has been used, and into which all the filth about the houses drains. Their small streams serve as washtubs for clothing, etc., as bathtubs for the entire town, as wallowing holes for domestic animals, and finally as a source of drinking and cooking water.

When these conditions are realized, and especially when we reflect that cholera, plague, typhoid, etc., are always present in many countries, the wonder is that any of these unfortunate beings survive. Fortunately, Providence has mercifully arranged, through the agency of severe rain storms, for the washing out of many of these filthy places, and through that of a hot sun for the roasting of a goodly portion of the organisms which survive the floods. Notwithstanding these natural prophylactic measures, a variety of circumstances—as, for example, the protection offered by the flora and fauna of the region, and the ignorance and poverty of the people—preserve all the conditions required for the propagation and dissemination of diseases. To this normal condition of disease-promoting factors there must occasionally be added the occurrence of a famine, due to a general failure in crops or to an epidemic among domestic animals, etc. Consequently, preventive medicine must battle, not only with these natural difficulties, but also with unlimited poverty, with ignorance, and with multitudes influenced by dogmatic religious beliefs.

Owing to their origin, education, etc., the nations occupying tropical countries have, with rare exceptions, been incapable of self-government. This fact, coupled with the possible gain of riches, has attracted the attention of civilized nations to the tropics and has led, in many instances, to the active commercial exploitation of these countries. Naturally, the resulting increased intercourse between tropical and temperate climates has awakened a new interest in all conditions prevailing in the tropics, has furnished a means for the introduction of tropical diseases into temperate climates, especially during the summer months, and has given to "tropical diseases" a new interest and a practical bearing. This impetus has, within the past few years, resulted in a rapid development of our knowledge regarding the etiology, course, and prophylaxis of "tropical diseases." Each advance indicates more clearly that the greater number of these diseases are infectious and consequently may be prevented, and that each step in preventive medicine renders the tropics more habitable for races accustomed to temperate climates. Our increased knowledge of tropical diseases enables us to identify, in temperate climates, diseases—such as ankylostomiasis, filariasis, etc.—which, without the knowledge so acquired, would escape recognition. Thus at home, in a temperate climate, we are exposed to many so called "tropical diseases."

As a result of modern interest in the tropics, of modern research in regard to the dissemination and prophylaxis of "tropical diseases," the monumental work of the late Major Walter Reed, United States Army, must be cited.

Lastly, as our knowledge of "tropical diseases" increases, the importance of their geographical and meteorological relations diminishes, and the conclusion is reached that they are equally as important to the medical men of temperate climates as to those of the tropics.

W. J. Calvert.

TRYPSIN. See *Pancreas*.

TRYPTOPHAN (PROTEINOCHROMOGEN).—In their classic work on "Die Verdauung nach Versuchen" (1831) Tiedemann and Gmelin noted the peculiar red coloration which pancreatic juice and the intestinal contents of animals gave with chlorine water. Claude Bernard failed to observe the reaction with *fresh* pancreatic juice. The researches of Kühne and his followers have indicated that the color reaction is due to a product of the cleavage of proteids, especially through the agency of pancreatic digestion. Kühne found that the characteristic reaction could be obtained equally well with bromine water, which is now more generally used in testing for the substance. If a mixture containing the rose-colored product of the reaction be shaken with amyl alcohol the colored product is taken up by the latter solvent and shows in this a characteristic spectroscopic absorption near the D line. The name *tryptophan* (from *θρύπτομαι* and *φαίνω*) was introduced by Neumeister as indicating the origin of the body in the decomposition of proteids. Stadelmann applied the less familiar term *proteinochromogen*, reserving the word *proteinochrome* for the colored compound of which the halogen (Br) forms a part. Trytophan is now known as a typical and constant product of the tryptic digestion of proteids. It may also arise when the albuminous substances are split up by baryta water, dilute acids, or the action of bacteria. When proteids are digested with purified pepsin or papain (?) it is not obtained. Glaessner has shown, however, that it is formed by the enzyme pseudopepsin, which is associated with true pepsin in the gastric membrane. Tryptophan may arise in the autolysis (self-digestion) of tissues, even in the absence of bacteria. The vegetable enzymes bromelin (from the pineapple) and nepenthin (from Nepenthes), as well as those from many other plants, also form products which are said to give the violet color with chlorine or bromine water.

In the earlier attempts to isolate and identify tryptophan, the chromogen was precipitated from its solutions in the form of the halogen compounds which are obtained with bromine or chlorine. The results were not constant, and the products of different investigators varied in their composition, owing to the difficulty of separating them completely from other decomposition products of the proteids, such as peptones. Accordingly various analyses have been reported which showed the compound to contain carbon, hydrogen, nitrogen, and bromine (or chlorine). Pyrrol and indol derivatives were obtained as decomposition products. Nencki regarded tryptophan as the mother substance of some of the pigments (melanins, etc.) which have their origin in the animal body. The latter yield similar products of cleavage.

Tryptophan was first isolated as such by Hopkins and Cole. In composition it corresponds with the formula $C_{11}H_{12}N_2O_2$; and it has been identified as skatol amido-acetic acid, which Nencki believed would be found as the precursor of those indol derivatives that arise during the putrefaction of proteids. The pure, colorless crystals show great proneness to undergo brown pigmentation on heating with acids, or even with water alone. Tryptophan thus isolated gives the well-known Adamkiewicz proteid reaction (with glacial acetic acid and concentrated sulphuric acid), which has been shown to depend upon the presence of glyoxylic acid in the acetic acid used. Solutions of the isolated tryptophan also give the "pine-slip" reaction direct, offering strong evidence of the presence of the pyrrol ring (or the indol nucleus). The investigations of Ellinger have made it probable that tryptophan is a precursor of indol in the putrefaction of proteids, and that it thus bears a direct relation to the indican of the urine.

For the methods of isolating tryptophan, the reader is referred to the papers of Hopkins and Cole. To test for tryptophan in solutions containing products of proteid decomposition, the following method is usually employed: The solution is acidified with acetic acid, and gradually treated with two or three volumes of saturated bromine water until a reddish-violet precipitate is formed. Large amounts of proteid may first be separated by precipitation with alcohol. The tryptophan is then searched for among the alcohol-soluble products, after removal of the alcohol by evaporation.

TUBERCULIN. See *Tuberculosis*.

TUBERCULOSIS.—An infectious disease caused by the bacillus tuberculosis.

HISTORICAL.—It is possible to divide the literature of tuberculosis into six periods. 1st. The description of the tubercle as a specific structure. 2d. The early clinical and anatomical study of phthisis and other lesions of the disease. 3d. The discovery of the infectiousness of the disease and the proof by this of the etiological unity of the lesions. 4th. The discovery of the bacillus and the proof that it was the cause of the disease. 5th. The discovery of tuberculin. 6th. The study of modes of infection and the part played by animals in the extension of infection.

1st. Although the word tubercle had long been used to designate a small nodule, it was not until 1793 that it was described by Bailey as a specific structure. He described under this name a special formation which he found in the lungs in cases of phthisis. The tubercles are small round bodies, never exceeding the head of a pin in size, and which are formed in the cellular tissue of the lung. Large tubercles can be formed by the union of small. The centres of the large tubercles are converted into pus, and this transformation of tubercles into abscesses is the cause of phthisis.

2d. Bayle in 1811 made an anatomical study of phthisis based on one hundred and nine autopsies. He defines as phthisis all lesions of the lungs which produce disorganization and destruction of the lung tissue. He characterizes phthisis clinically as an *ensemble* of symptoms consisting in cough, dyspnœa, marasmus, hectic fever, and sometimes purulent expectoration. Anatomically he distinguishes six varieties of phthisis, but gives special importance to the first two, tuberculous phthisis and granular phthisis.

In tuberculous phthisis the lung contains tubercles formed of an opaque homogeneous substance having a whitish-yellow or grayish color. These tubercles are at first firm, but they afterward soften in their centre, and are finally destroyed by suppuration. The tuberculous affection is a chronic disease of a special character, but probably of a scrofulous nature, and should not be regarded as the result of inflammation. The second variety, granular phthisis, often accompanies the first. In this the lungs are filled with miliary transparent granules of cartilaginous hardness, from the size of a millet seed up to that of a grain of wheat. These granules are not exclusively localized in the lung, but may be met with in the peritoneum, intestine, and heart. This is the first description of miliary tuberculosis.

In 1826 Laënnec proclaimed from his study of pathological anatomy the unity of the different forms of phthisis, and he found the characteristics of the disease in the evolution of the tubercle. "The progress of pathological anatomy has demonstrated that pulmonary phthisis is due to the development in the lungs of a peculiar formation which has received the name of tubercle. The tuberculous material develops in the lungs and in other organs in two principal forms, as isolated bodies and as infiltrations. Each of these forms presents a number of varieties due chiefly to their different degrees of development. The isolated tubercles present four varieties which may be distinguished as miliary tubercles, crude tubercles, granulations, and encysted tubercles. The tuberculous infiltration presents three varieties which can be designated as crude tuberculous infiltration, gray tuberculous infiltration, and yellow tuberculous infiltration. Whatever may be the form into which the tuberculous material finally develops, it presents in its origin the appearance of a gray or semitranslucent mass which gradually becomes yellow, opaque, and very dense. It finally softens, becomes almost as fluid as pus, and is expelled by the bronchi, leaving in its place cavities commonly known as ulcers of the lung, and which we designate as tuberculous excavations." Laënnec also recognized the specific character of these lesions. "One cannot regard the tubercles as the result of inflammation of some one of the constituents of the lung without destroying the results of observation and making a strange abuse of reasoning. If inflammation has any influence on the appearance or the development of the tubercles, it is only to prepare the soil and make it favorable to their growth; in the same way as the soil when cultivated after a long repose will germinate a multitude of seeds which have lain in it for a number of years."

The views of Laënnec prevailed generally until the more careful anatomical investigations of Virchow. In his work on the lymph glands Virchow says: "More careful observation shows that the scrofulous affections of the lymph glands are secondary, and not due to any preceding blood crasis or any general change in the character of the blood, but secondary in relation to the local changes of those parts from which the glands obtain their lymph. The gland swelling is due to certain substances produced in consequence of pathological processes, which are carried over in the lymph to the next lymph nodes and produce in them similar irritation. This can take an inflammatory character or a progressive development without evidences of inflammation. The condition is called scrofula when slight irritation produces extensive glandular swellings. In certain individuals the swelling continues, and this is the reason why it appeals to some as an independent process. The condition is connected with a weakness of the individual or of certain parts of the body. This constitution can be acquired, as is shown by the frequency of such conditions in prisons, where the nutrition of the inmates is not sufficient. The signs of this weakness are a diminished capacity of resistance of the tissue toward disturbances and slighter powers of recuperation." After describing the caseation of the products of inflammation in the lymph glands he says: "A similar condition can take place in the inflammatory products of a mucous membrane when these remain for a considerable time at the place of their formation. They also become thickened and caseous. This takes place in no other part so often as in the lung, where the alveoli and small bronchi become filled with such caseous masses, and that condition arises which, since Laënnec, has been given the name of tuberculous infiltration, and which I consider as caseous infiltration or caseous hepatization. This may involve entire lobes of the lung, or it may be limited to single sections of the lung and then corresponds to what is ordinarily described as crude tubercle. Sometimes it is limited to small groups of lung alveoli; then it is miliary caseous hepatization. There is nothing that justifies us in considering these masses as tubercles. Along with this, tuberculosis can take place, but the tubercles are seated in the walls and not in the lumen of the air passages."

Virchow described the tubercle on the other hand as an organized structure, a neoplasm. It has a cellular structure, but is not vascular. It arises from the proliferation of pre-existing structures and is never an exudation. The larger tubercles are formed from the union of a number of small tubercles. These sharp, precise views of Virchow represent a great advance.

They were purely anatomical, and based on his studies of the histogenesis of pathological processes. His knowledge of microscopic structures enabled him to separate a new formation of tissue from an exudation. It was perfectly logical from such a study to make the distinctions which Virchow made. Laënnec's idea of the unity of the process was based on similarity of the gross appearances, and he was probably also influenced by his clinical knowledge of the disease, finding the same general clinical course in the various types of the lesions. There is no histogenetic unity of the tuberculous lesions, the only unity is the etiological one which was given by the work of Villemin and Koch.

3d. The infectiousness of the disease. Koch in his work on tuberculosis gives Klencke (1843) the credit for the discovery of its experimental transmission, but says he did not continue his experiments, and they were forgotten. Klencke's experiments on tuberculosis were undertaken in accordance with his idea that contagion was carried by pathological cells which have the power of generalizing an affection. He says he has been able to transmit cancer and melanosis, by intravenous injection of the cells, from man to the dog and cat. The tuberculous cells are capable of being transplanted in the same way. Tuberculous cells prepared by one of his assistants were introduced into the jugular vein of a rabbit, which when killed six weeks afterward showed extensive tuberculosis of the liver and of the lungs. The rabbit served to inoculate a crow, but without result. Although there is no doubt that Klencke did succeed in transmitting the disease, it in no way detracts from the credit of Villemin. Villemin (1865) showed that rabbits inoculated subcutaneously with tuberculous material from a man, from a cow, and from a rabbit became tuberculous. At the end of twenty to thirty days the animals began to emaciate and finally died in a state of extreme cachexia. The autopsies showed tuberculosis of the lymphatic ganglia and a formation of tubercles in the viscera and on the serous membranes. Cohnheim, in his celebrated address on tuberculosis, gives Villemin the credit of the discovery. He says: "At this time a discovery was made in France which not only marks an incomparable advance in the history of tuberculosis, but from which must date a complete change in the general conception of the process. There have been few discoveries which have so influenced medical thought as Villemin's proof of the transmission of tuberculosis. Wherever scientific work was carried on, head and hand were set in motion to repeat Villemin's experiments and to prove his views."

In 1868 Chaveaux produced tuberculosis in three heifers by giving them, by the alimentary canal, tuberculous material from a cow. He confirmed the work of Villemin and concluded that the alimentary canal constituted in cattle as in man an important channel of infection, and one more common than the air passages.

4th. The first publication of Koch in which he described the tubercle bacillus, its mode of culture and relation to the lesions of the disease was made in 1882, and was followed by a further paper in 1884. This is the most important contribution to our knowledge of the disease, and ranks among the most important contributions to medical knowledge. It marks the beginning of an enormous increase in the literature of tuberculosis, and did more than any other publication to stimulate research in infectious diseases. The structure and the histogenesis of the tubercle were studied by animal experimentation. The presence of the bacillus and the capacity of producing the disease experimentally were shown to be the criterion of what was tuberculosis. Every doubt as to the unity of all processes in which the bacillus was found, however varying their anatomical characteristics might be, was removed. The term scrofula disappeared from medical nomenclature.

5th. No less stimulating was Koch's discovery of tuberculin in 1890. He considered this the active chemical substance which was produced by the bacilli, to which important symptoms and lesions were due. The high hopes which he had of tuberculin in the therapy of the disease have not been entirely realized, but, from the work which the discovery of tuberculin stimulated, our knowledge of the disease has been greatly increased. More attention was directed to the study of the bacillus and its varieties.

6th. In the last period of the literature, which is not marked by any special publication and may be said to begin about 1898, attention has chiefly been directed to the study of the comparative pathology of the disease, modes of infection, and immunity. Methods of diagnosis have been made more accurate, the importance of early diagnosis has become more appreciated, and rational systems of prevention and treatment have been inaugurated.

The Bacillus.—The bacillus tuberculosis is a small, non-refractive, rod-shaped organism, generally from 2 to 2.5 μ in length, or from one-quarter to one-third the diameter of a red blood corpuscle. It is not motile, is usually slightly curved, and both in the lesions and in sputum is more often found in small groups than singly, the small groups of two or three bacilli representing those which were contained in a single cell. There is considerable variation in the morphology. Organisms are found which are much longer or shorter than the ordinary forms, and in recent years a number of observers have described, both in sputum and in old cultures, long, branched, and club shaped forms similar to the branched forms of the diphtheria bacilli. In many cases the bacilli do not stain homogeneously, but represent a striking alternation of unstained and brightly stained points, resembling a short chain of streptococci. Such forms are frequently found in the sputum, and the unstained points have been considered to be spores, but there is nothing in the life history of the organism to justify us in the belief that spores are produced, nor do the unstained areas have the refraction so characteristic of spores. This irregular staining is best shown by staining the bacilli intensely with fuchsin and decolorizing with sulphide of soda. The bacilli stain with difficulty. Staining reagents seem to penetrate with difficulty, but when stained they retain their color under conditions in which other bacteria are decolorized. It is this property which enables their detection and differentiation from other organisms. The best method for their detection in fluids is staining with carbol fuchsin with following decolorization in Gabbet's stain (two-per-cent. alcoholic solution of methylene blue in twenty-five-per cent. sulphuric acid). In tissues they are best stained by the method of Kühne, which consists of staining in warm carbol fuchsin, using hæmatoxylin as a counter stain and decolorizing in Orth's discharging fluid.

Their detection in sputum is a matter of great practical importance, for it is on this that the diagnosis of lung tuberculosis is principally based. The morning sputum coughed up by the patient should be examined. This should be spread out on a dark plate and the more opaque consistent particles picked out and spread on a cover slip in a thin layer. The cover slip is then dried and heated over a flame to render the albumen insoluble. Several drops of carbol fuchsin are placed on the dried surface, the cover slip is then boiled over the flame and placed in Gabbet's fluid for one to two minutes for decolorization and counter stain. The bacilli are usually fairly abundant in the sputum of cases of lung tuberculosis, and there is no difficulty in their detection. Occasionally small, hard masses may be found in the sputum, especially in cases of advanced tuberculosis with cavity formation, which are entirely composed of tubercle bacilli, and which represent pure cultures of the bacilli growing on the walls of the cavities. I have several times seen such masses in the sputum after the use of tuberculin. The positive diagnosis of the absence of bacilli can be made only after repeated examination of carefully selected portions of sputum, or by boiling the sputum in two-per-cent. caustic potash and examining the sediment. The sputum may also be digested in pancreatin and the sediment examined. In the lesions in the tissues the bacilli occur in extremely variable numbers, and the examination of numbers of sections may be necessary to detect them.

There are few bacilli with which they may be confounded. They closely resemble the leprosy bacilli, but it can rarely happen that the question of differential diagnosis from these can come up. The leprosy bacilli stain with carbol fuchsin in the same way, but they also stain with the ordinary bacterial stains. There is much more danger in confounding them with other bacteria of the acid-resisting group, such as the smegma bacilli and a bacillus frequently found in hay and in dairy products. There can be little doubt that these bacilli have been frequently confounded with the tubercle bacillus, the former in the examination of urine, and the latter in the examination of dairy products. The tubercle bacilli can be distinguished from these by the fact that they retain their color in alcohol after they have been differentiated, while the smegma and the hay bacilli are decolorized. There may even be difficulties in the inoculation test, for the hay and butter bacilli produce in rabbits and guinea-pigs nodules which closely resemble tubercles, though they lack the characteristic caseation.

The tubercle bacillus was first grown in pure culture by Koch on solidified blood serum. But little can be added to his description of the growth. In from ten to fifteen days the first sign of growth appears as dull white points or specks on the surface. These cling lightly to the surface and appear as dry scales. According to the amount of material used for inoculating the surface, the abundance of bacilli contained in it, and their distribution on the surface, there is a greater or less extent of surface covered by the scales. At first the single scales are separate, but finally they become joined and form a thin grayish-white coating over the surface. On transplanting to fresh tubes more bacilli are carried over, they are more homogeneously distributed, and the growth forms a connected membrane. The extension over the surface is not caused by the wandering of the bacilli, nor by the bacilli piling over the edge, but by the membrane being shoved over the surface by the continual growth. The bacilli never liquefy the serum, nor do they grow into it, but always remain on the surface. At the edge of the growth the small masses of bacilli have peculiar forms when examined under the low power. They grow in fine, bent, or curved lines, often having the shape of the letter **S**. The ends of the masses are pointed and the middle is swollen, giving them a spindle shape. When the bacilli are very numerous in the tissues they may appear in masses having this form. Such masses may be seen in the walls of tuberculous cavities of the lungs and in the tubules of the kidneys. (Plate LVI.)

TUBERCLE BACILLI.

FROM R. KOCH'S "*DIE AETIOLOGIE DER TUBERCULOSE*"

Mittheilungen aus dem Kaiserl. Gesundheitsamte. Berlin 1884

Blood serum remains on the whole the best medium for the growth of the bacilli, especially for obtaining the primary growth. An important addition to the technique of their growth was made by the discovery that glycerin added to the culture media facilitated growth. The bacilli grow readily on agar and bouillon to which glycerin has been added. It is very difficult to obtain a pure growth of the bacillus from sputum, or even from the tissue lesions in man, owing to the liability of contamination with other organisms. Kitasato was the first to obtain a pure culture from sputum. The culture is usually obtained by inoculating an animal and using its tissues for cultivation. The advantage is that the bacilli are abundant, and if the animal has been killed there are no contaminating organisms. Smith has shown that it is better to use considerable portions of the tissues for inoculating the tubes, as the bacilli have become accustomed to growth in such tissue. Growth becomes more easy in every subculture as the bacilli become accustomed to a saprophytic existence. The bacilli in pure culture adhere together in masses which are difficult to separate, so that it is difficult to obtain a homogeneous mixture of them in a fluid. Hesse has strongly recommended, for cultivating the bacilli from a sputum, a medium containing a soluble albumen preparation known as Nährstoff Heyden. He obtained upon agar containing 0.5 per cent. of this substance along with three per cent. of glycerin a characteristic microscopic growth of the bacilli from tuberculous sputum in three days. Even when other bacteria are present, the commencement of the tubercle growth can be demonstrated in contact preparations in five or six hours. This is the best medium for obtaining a primary culture from sputum, though it is not the best medium for their continued growth.

The tubercle bacilli are not saprophytic under natural conditions. They grow only within narrow limits of temperature, and will not find favorable conditions for growth outside of the animal organism. The temperature limits of growth are 30°–42° C. Growth takes place best at a temperature of 39° C. Cultures will usually become sterile after twelve months. Bacilli in dried sputum kept in the dark may remain virulent for from six to ten months. The sputum does not lose its virulence by alternately moistening and drying. The dried sputum in a chamber, exposed to diffuse daylight, may retain its virulence for two months. Putrefaction does not destroy the bacilli, but they are rapidly killed by sunlight. Smith has shown that a temperature of 60° C., maintained for twenty minutes, will kill the bacilli in water, salt solution, bouillon, and milk, but that a membrane formed on the surface contained living bacilli after sixty minutes' exposure to this heat.

Fatty acids are important constituents of the tubercle bacilli, and Unna has supposed that the resistance of the stain to acids depended upon these fats. Aronson has shown that the body which gives the acid resistance is of the nature of a wax, and when this is removed the stained bacilli are no longer acid-proof. The best analysis of the tubercle bacilli is that of Rüppel. He finds in 100 gm. of dried tubercle bacilli: Fat and wax, 26.5; nucleic (tuberculinic) acid, 8.5; protamin, 24.5; nucleo-proteid, 23; mineral substances, 9.2; proteinoid substance, 8.3. According to Behring the nucleic acid possesses in high degree the specific properties of Koch's tuberculin.

Levene found differences in the composition of the bacilli dependent upon the medium on which they were grown.

A substance called *tuberculin* is present in cultures of the tubercle bacilli and in the infected tissue. It may be extracted from the dead bacilli and represents the sum of their proteid substance. It is not known whether it is actually given off from the living bacilli as a secretion, analogous to diphtheria and tetanus toxin, or whether it is exclusively derived from their protoplasm. Koch first described this substance and its action at the International Medical Congress in Berlin in 1900. As first prepared it was known as crude tuberculin. The bacilli are grown in large dishes, which give a large surface to the growth. The culture medium used is bouillon containing one per cent. of peptone and from four to six per cent. of glycerin. The bacilli grow abundantly in this, forming a thick yellowish membrane on the surface. After six weeks growth ceases and the membrane begins to break up and sink to the bottom. The culture is then evaporated to one-tenth its volume on the water bath and the residue filtered through porcelain. Tuberculin as so prepared is a brownish fluid, the color being due to the concentrated color of the bouillon, and contains enough glycerin to preserve it indefinitely. It evidently represents a number of different things, including a concentration of the soluble substances of the bouillon. Later, Koch attempted to purify the product by extracting the pulverized bodies of the dead bacilli. He produced two substances, one soluble in water and one soluble in glycerin. The material soluble in water has the same action as the crude tuberculin. Koch was led to the therapeutic use of tuberculin by the difference which he found in the inoculation of a healthy and a tuberculous guinea-pig with a virulent culture of the tubercle bacilli. In the normal animal subcutaneous inoculation leads to the formation of a tuberculous ulcer, which persists until the animal dies from generalized tuberculosis. If a second inoculation is made five or six weeks after a primary, only induration and necrosis of the tissue at the site of inoculation are produced. The necrotic tissue is thrown off and the ulcer heals by cicatrization. He found the same results from the dead bacilli, and endeavored to obtain the chemical substance which was present in the body, and which caused the second inoculation to take a more favorable course. In his explanation of the action of the remedy he supposes that the bacilli produce substances injurious to the cells, causing them to undergo coagulation necrosis. Such necrotic tissue forms a bad culture medium for the bacilli and they die. A greater amount of this substance causing necrosis will extend the area and still more wall off the bacilli contained in it. The necrotic material may become detached and remove the bacilli contained in it outside of the body. The tuberculin contains the material which produces the necrosis, and when injected in sufficient amounts into a healthy man will cause fever and toxic symptoms. Very small doses injected into a tuberculous subject will cause fever and other symptoms. It also exerts a local action on tuberculous tissue, producing intense hyperaemia with leucocytic invasion and increasing the extent of the necrosis. It has this intense general and local action in the tuberculous subject by increasing the amount of tuberculin in the fluids and in the local lesions, some being always formed by the bacilli in the affected subject. This hardly explains its action because a severe general and local reaction takes place when the tuberculous lesions are so slight as scarcely to be manifest, and it can hardly be supposed that in such lesions, containing only a few hundred bacilli, an appreciable amount of tuberculin can be produced. It is generally considered that the action of tuberculin is specific, that its local and general action in very small doses, 0.1–1 mgm., is exerted only in tuberculous individuals. There are opposing opinions to this view of specific action. Roemer and Buchner have obtained the tuberculin reaction in tuberculous guinea-pigs with extracts of other organisms. Tuberculin reaction has been obtained in man in cases of syphilis and in other infections, and in individuals who were clinically in perfect health. In these cases it is impossible to say that an individual giving the tuberculin reaction has not some focus of latent tuberculosis. Koch regarded the remedy as directly curative in the early stages, the advance of the disease being stopped and the lesions cicatrized. The most enormous literature on tuberculin followed the publication of Koch. Every physician who could obtain any of the precious fluid published his results, however insignificant they might be. The remedy seemed to have a more decided and favorable action in tuberculosis of the skin than in any other forms. Portions of tissue here can be excised and the influence exerted on the lesions followed. Its general action was seen to be the production of acute inflammation in the lesions with leucocytic infiltration and serous and fibrinous exudation. The general results were not favorable to the views of Koch. Numerous autopsies were made on cases of tuberculosis in which the remedy had been used. It was shown that it could be dangerous and even fatal, producing extensive inflammation around foci in important organs and leading to dissemination. The strongest possible reaction succeeded the enthusiasm with which the remedy was first greeted. At present it seems to be the opinion that tuberculin is of great importance in the diagnosis of tuberculosis in animals (cattle) and in man, being far more accurate than any other mode of diagnosis with the exception of the bacteriological and experimental; it is available when these methods are not. It is of therapeutic value in certain early cases, and when most judiciously used. It is a very dangerous agent when considered as a general remedy for the disease.

Differences in Bacilli.—In his first work Koch held that there was but one species of tubercle bacillus, and that all forms of the disease in man and in animals were the same, and due to the same bacillus. Subsequent study has shown that this statement must be greatly modified, and that there are several distinct varieties or strains of the bacilli. These different strains are distinguished from one another less by their morphology and cultural characteristics than by the effects which they produce on inoculation. The general opinion seems to be that they cannot be made to pass one into the other either by cultures or by series of inoculations. Undoubtedly much confusion in the pathology arises from these variations. It will be necessary to repeat a great deal of the work which has already been done, holding in mind these differences and in every case determining the character of the organism which has been used in the experiments. These different strains of bacilli will be considered in the tuberculosis of animals.

Differences in Virulence.—Great differences are found in the clinical course of the disease and in the character of the lesions. In certain cases the disease runs its course, ending in death, in a few weeks or months; in others it takes a very chronic course, and may terminate fatally only after years. Autopsies show an extraordinary number of cases in which infection has been followed by cure or at least by complete quiescence of the disease. In the microscopic study of the lesions the same differences are seen. In one case little or no reparative action of the tissue; in another a formation of fibrous tissue, limiting the extension of the process. These differences are due to a number of factors: The anatomical structure of the organ attacked, which may or may not favor the dissemination of the bacilli or the chemical substances derived from them; the number of bacilli and their mode of entrance into the tissue; peculiar individual qualities of the tissue attacked or of the body generally.

There is undoubtedly a great difference in the organs and tissues attacked as regards their favoring or not the multiplication of the bacilli, this difference being due not to anatomical arrangement, but to peculiarities probably of a chemical nature. It is possible also that there may be differences in different individuals, the bacilli finding all or similar tissues in one more favorable for growth than in another. It is generally assumed also that there are differences in the virulence of the bacilli. There are certainly differences in the virulence of the different strains of the bacilli, the bovine being most virulent, the human coming next. The virulence of cultures also diminishes in the course of cultivation. There is some uncertainty as to the variation in virulence of primary cultures of the human and bovine, and whether we can refer differences in the lesions and in the clinical course of the disease to this. Variations in the virulence of human cultures may be due to infection with other than the human bacillus. Vagedes has studied the virulence in thirty different cultures of the bacilli. Three were from rabbits which had been inoculated, two were from cattle, and the others were obtained directly from the human sputum or from contents of cavities. He tested the virulence by inoculation with a suspension of the bacilli made by rubbing up weighed amounts of the pure culture in a given amount of water. He found three different degrees of virulence, four of the cultures derived from man being as virulent as the bovine. The most virulent culture came from a fifteen-year-old girl, both of whose parents had died of the disease. The autopsy of the girl showed advanced lesions of the lungs and intestines. The less virulent cultures came from the cases which clinically showed a less rapid course. There was very little difference in the character of the growth in the different cultures. One culture of medium virulence resembled the avian type of bacillus, and there was much similarity in the shape of the organisms between those from his most virulent case and the bovine.

Tuberculosis in Animals.—The disease never appears in animals in a wild state. In some it never appears spontaneously, though they may be highly susceptible to inoculation. The same rules for infection govern the disease in animals and in man, being dependent upon the situation of the lesions, this determining the ways by which the bacilli leave the body and the opportunity given by the life of the animal for the entry of the bacilli into the tissue. The disease in animals is of great importance, both from the enormous economic loss it entails and because animals play a certain part, the importance of which is probably overestimated, in the transmission of the disease to man. It is also of importance that the disease can be given to animals, because our knowledge of the disease has been chiefly obtained through animal experimentation. The unity of the disease could have been established only by animal inoculation. Modes of infection followed by preventive measures have been studied in the same manner.

Tuberculosis of cattle is the most common and the most important form of animal tuberculosis. The form of disease differs in many respects from that in man, and the identity of the two has been established only in the last twenty-five years. It is characterized chiefly by the presence of hard, tumor-like masses up to 20 cm. in diameter, on the serous surfaces or in the viscera. The masses are often flat on top and attached to the surface by a pedicle. Several such masses may be united together by small attachments, and hang from the serous surface like a bunch of grapes. The large masses are formed from the confluence of single tubercles, which give the surface an irregular character. The smaller nodules are hard and fibrous on section, later they become caseous, infiltrated with lime salts, and have a peculiar bright-yellowish color. They may undergo partial softening, becoming filled with a yellowish, greasy, gritty material of the consistence of mortar. Microscopic examination of the younger nodules shows a structure composed of single tubercle with epithelioid and giant cells containing bacilli. The lungs contain irregular solidified areas, circumscribed tumor-like masses similar to those first described, and cavities with smooth walls, filled with yellowish, thick, tenacious, often fetid material. The extension along the bronchi is very evident, the separated single lobules are often affected, the single small foci in these resembling the grapes on a bunch, the stems being represented by the bronchi filled with and surrounded by yellow caseous material. The lymph nodes are always infected, and may be the only seat of the disease. Infection seems to take place chiefly by inhalation and the bronchial and mediastinal nodes are those most often affected. The nodes may be enormously enlarged, forming hard caseous or calcareous masses with peculiar yellow pigmentation. The grayish tumor-like masses have given the disease the name "Perlsucht," or pearl disease. Acute general miliary tuberculosis as seen in man does not occur, though miliary tubercles harder and more transparent than in man may be found both on the serous surfaces and in the organs. Ulceration of mucous surfaces is not common, although in the trachea and larynx ulcers may be found which take the form of large projecting masses formed of conglomerate tubercles, and which seem to have burst through the mucous membrane. I have seen one case in which tuberculosis of the peritoneum took the form of a diffuse caseation of the surface with adhesions between the intestines which were filled with communicating ulcers, the whole forming a mass which it was impossible to disentangle. Tuberculosis of the mamma is common and important from its relation to the infection of milk. It may be primary or a part of the general process. It usually commences as a diffuse uniform thickening of the posterior part of the gland. The gland at this time may contain bacilli which are apparently growing in the ducts, since they can be squeezed from it through the udder. Later, the gland becomes filled with fibrous or caseo-calcareous masses, and increases greatly in size. The milk may present a normal appearance, even when there is advanced disease of the gland; later, it becomes thin, bluish, and on standing gives a sediment which contains numerous bacilli. The bones are rarely affected.

The disease ordinarily takes an extremely chronic course, and may remain latent for years. The animals may become fat, appear to be perfectly well, and yet the autopsy shows an advanced tuberculosis of the serous cavities. When the disease takes a more rapid course, cough begins, there are fever, discharge from the nose, and rapid emaciation. The disease is widely spread over the entire civilized world. It increases in a definite proportion with age, and is extremely rare in calves. Most cases are in cattle over six years of age. It is more frequent in cows than in oxen and bulls, which may in part be due to the more confined life of the cows and the greater demands made on their nutrition by pregnancy and lactation; but it is probably due rather to the fact that cows live longer. The disease spreads by contagion and one animal may infect a herd. The opportunities are good for the extension of the infection. The animals are usually in close proximity, they cough forcibly, and can project fine spray particles of sputum containing the bacilli for a considerable distance; they commonly use the same place for drinking, they lick away their nasal discharge, and by the habit of licking each other may transfer the bacilli. The disease is most common in stables where the animals are kept closely confined.

There is much difference in the susceptibility of the different breeds of cattle. The purest breeds where the selection of certain qualities economically valuable has been made are those most affected. The most susceptible races are the Alderneys and the Short Horns. Certain strains of these in England have been threatened with total extinction. Wilson estimates that in Great Britain there are 2,200,000 tuberculous cattle, and that the annual loss caused by the disease is £3,000,000 sterling.

The numbers of bacilli found in the lesions vary. They are about as numerous as in the human lesions, and they may be present in enormous numbers. The greatest number of bacilli I have ever seen in a disease was in a case of intestinal tuberculosis in a cow.

The most important practical question relating to bovine tuberculosis is the part which it plays in the transmission of the disease to man. The danger comes through the use of the milk; the danger of infection through the use of the meat of tuberculous animals is remote. Tubercle bacilli have been repeatedly found in milk and in milk products. They are always present in large numbers in the milk in tuberculosis of the udder, and may be present in tuberculosis of internal organs when the udder is not affected. When we consider the enormous frequency of bovine tuberculosis and the facts that the milk coming from different farms is all mixed before distributing in the cities, and that the bacilli would certainly not be destroyed in the milk, it is evident that they must be frequently ingested. But a small proportion of the milk used in this country is boiled or even heated before it is used. Animals fed on milk containing bovine bacilli become infected, but the opinion is gaining that milk infection is an exceedingly rare source of tuberculosis in man.

Baumgarten (1882) was the first to point out differences in the transmission of the bovine and the human disease. He says that inoculation with material from bovine tuberculosis produced a disease which took a quicker course and led more rapidly to a general infection than inoculation with material from man or dog. He had no results from the inoculation of tuberculous material from chickens and pigeons.

The bacillus of bovine tuberculosis is the common cause of all tuberculosis in mammals with the exception of man. The morphological distinctions between the human and bovine bacilli are not sufficiently marked to enable us to distinguish them. The bovine bacillus is a little shorter than the human and the sizes are more constant. The cultural differences are more marked. The human bacilli from the start grow more vigorously than the bovine, though the bovine are less influenced by slight modifications of the culture media. There are marked differences in the character of the growth on the surface of glycerin bouillon, the growth of the bovine forming a more moist and translucent membrane with less tendency to plication. The inoculation differences are more striking. The bovine is more virulent for all animals and tends to more rapid generalization. When rabbits are inoculated in the ear vein with like amounts of pure cultures of the human and bovine bacilli the bovine inoculation produces general miliary tuberculosis and death in three weeks. With the human bacilli the animal lives longer and may survive the inoculation. A number of inoculations in cattle have been made with pure cultures of both bacilli and with somewhat varying results. But the general result shows that cattle are either completely immune to the human bacillus, or, if they acquire the disease at all, only slight local lesions are produced. The study of the bacilli shows that the characteristics of each form are retained after a series of cultures and animal inoculations. Those opposing the idea that the disease may be transmitted from cattle to man base their belief on a number of conditions. The types of human and bovine bacilli remain constant, and only the human type is found in pure cultures of the lesions in man. Bovine tuberculosis cannot be produced by inoculation of the human bacillus. Were infection by milk common, the lesions in man would show the primary foci in the intestinal canal. Experiments in feeding animals with tuberculous material produce a series of lesions pointing to infection from the alimentary canal. Primary intestinal tuberculosis or even primary tuberculosis of the mesenteric glands is rare in man, notwithstanding the opportunities for infection given in the extended use of milk. Baumgarten has recently reported a series of experiments made twenty years ago, in which inoculations of the bovine bacilli were made in man. Proceeding from the views of Rokitansky regarding the opposition between tuberculosis and cancer a physician inoculated a number of patients having advanced malignant tumors with pure cultures of bovine bacilli, with the hope of effecting a cure of the cancer. No influence was exerted on the cancer, of which the patients died, and at autopsy no effects from the injection of the bacilli could be found. Opposed to this there have been a number of cases reported of local and general tuberculosis in man due to infection with bovine tuberculosis, and some of them do not admit of any doubt. The matter of this mode of infection or the frequency of it is one which must be cleared up by further investigation. The permanence of type of the bacillus must be more accurately determined, and the bacillus must be isolated and studied in a large number of human cases, particularly in those in which infection seems to have come from the alimentary canal. The infrequency of primary tuberculosis of the alimentary canal is by no means opposed to the probability of food infection, because it is possible for the bacilli to enter the tissues without the production of a lesion at the point of entrance, or without any anatomical evidence of the lesion. No effective control of bovine tuberculosis is possible. To use the tuberculin test for its detection and to destroy all cattle which give the reaction would result in economic losses impossible for the state to meet. It would be absurd to condemn as unfit for consumption the meat of cattle which show only a caseous lymph node as evidence of the disease. In Massachusetts an attempt was made to exterminate the disease by destroying all cattle which gave the tuberculin test, but it was soon abandoned. The attempt at extermination of the disease in the present state of our knowledge regarding infection should be undertaken rather as an economic than as a hygienic measure. It might possibly be done by the general Government, but not by the States. At present in Massachusetts State control is limited to inspection of herds and destruction of cattle with evident extensive tuberculosis or with involvement of the mammary gland.

Tuberculosis of the horse is rare; the disease is often confounded with glanders, especially the chronic form of this. It is usually localized in the lungs and abdominal cavity, and resembles the bovine disease. The affected lymph nodes may form enormous tumors. Histologically the disease is characterized by the fibrous character of the tubercles, the less tendency to calcification as compared with cattle, the number of bacilli in the lesions, and their almost constant presence in the giant cells. The symptoms are not characteristic, and are not seen until a late stage of the disease. After cattle swine are most frequently affected. The disease is most often seen in young animals, and is due to infection by the digestive tract caused by feeding them with tuberculous milk or with the refuse of abbatoirs. A peculiar form of intestinal tuberculosis is sometimes seen in very young pigs, consisting in general diffuse necrosis and caseation of the mucous membrane. The lesions closely resemble those of diphtheritic dysentery. The disease often becomes generalized with great rapidity and takes an acute course. The bacilli are usually present in very small numbers. Sheep and goats are rarely affected, although the disease can be conveyed by inoculation. It takes the same form as in cattle. In Prussia in 1894 abbatoir inspection showed only 0.06 per cent. of tuberculosis in sheep. The dog, though relatively immune, may contract the disease. Villemin produced the disease in the dog by subcutaneous inoculation. Both the human and the bovine disease may be inoculated. Strauss has injected pure cultures of the human bacillus into a vein, producing miliary tuberculosis of the organs. Several cases of spontaneous infection of the dog have been reported, infection being due to the animal eating the sputum of a tuberculous master. The bacilli in the lesions are in very small numbers. Shortly after the discovery of the tubercle bacillus I had occasion to examine the tubercles in the liver of a dog for bacilli. The case was an important one at the time because it was regarded as proving the presence of tubercles without bacilli. Forty sections were examined before a bacillus was found. Tuberculosis can be easily transmitted to the cat, but the spontaneous disease is rare. The lesions have nothing characteristic. In one case of spontaneous tuberculosis the liver contained very acute lesions full of bacilli, and in many places there was an actual injection of the capillaries with masses of tubercle bacilli. It has been known for a long time that tuberculosis is frequent in monkeys living in captivity. In this animal, as in man, the pulmonary form is most common, and the lesions are very similar to those in man, though the tubercles have a greater tendency to softening and may resemble abscesses. The bacilli are present in about the same numbers as in man. The guinea-pig and the rabbit, although so susceptible to experimental tuberculosis, are rarely spontaneously affected even when in captivity. It is very rare in the laboratory, even when animals are kept in close relation with those infected experimentally, that an animal killed for any other purpose will show tuberculous lesions. Mice and rats are less susceptible than guinea-pigs and rabbits.

The tuberculosis of fowls has a special interest because it is due to a strain of the tubercle bacillus which is different from both the bovine and the human form. Infection takes place from the alimentary canal, though the mucous membrane shows no ulceration. The lesions take the form of small firm tumor-like masses seated principally on the peritoneal surface of the intestine and in the liver. The tumors are surrounded by a capsule of connective tissue and are easily enucleated. The tubercle bacilli are more abundant than in the lesions in any other animal. Section of a large nodule shows a necrotic centre which is full of bacilli. Around this is a layer of tissue containing epithelioid and giant cells in which the bacilli are less numerous. The bacilli are generally longer than the human bacilli, and the cultures can be distinguished from both this and the bovine. All experimental evidence is opposed to the idea that the human bacillus can produce tuberculosis in fowls. Strauss fed eight chickens with sputum rich in bacilli, and also gave them a chopped-up tuberculous lung. The autopsy showed no trace of tuberculosis, although masses of the tuberculous material were ingested. Martin has inoculated chickens and pigeons in the peritoneal cavity without producing any lesions. Subcutaneous inoculation of the human bacilli may produce an abscess at the point of inoculation. The results of the inoculation of the guinea-pig with the avian bacilli are distinctly different from those produced by either the human or the bovine varieties. An abscess follows subcutaneous inoculation but it does not open and produce an ulcer. The animal usually dies after some months, and at the autopsy abscesses are found at the seat of inoculation, enlargement of the lymph nodes, and a few tubercles elsewhere. The rabbit has an abscess at the point where it was inoculated, and the bacilli are not usually found elsewhere. The injection of the bacilli into the blood produces emaciation and death in the course of some weeks. The liver and spleen are enlarged and the vessels contain numbers of bacilli, but there are no tubercles.

Dubard and Terre discovered in 1897 a form of tuberculosis in carp; it was due to a bacillus, the bacillus tuberculosis piscium, which has the same staining reaction as other varieties of the bacillus, but which will not produce the disease in birds or mammals and grows at ordinary air temperatures. The cultures much resemble the human and avian forms. Frogs are susceptible to inoculation with the bacilli; the lesions are much the same as in other forms of tuberculosis, but caseation is not so evident. This bacillus contains a toxin with properties analogous to those of the tuberculin of Koch. Ledoux prepared these two toxins, making them as much alike as possible. Both the fish and human tuberculin produced a reaction in guinea-pigs inoculated with human bacilli, but the fish tuberculin was not so strong as the human. One cubic centimetre of Koch's tuberculin killed a guinea-pig which had been inoculated twenty-eight days previously. The same dose of fish tuberculin produced the same elevation of temperature, but was not fatal.

Tuberculosis in Man.—Mortality statistics from all civilized countries show that about one-seventh of all deaths are due to tuberculosis. This must be based to a large extent on the deaths in which the form of the disease is obvious. Every pathologist is aware of the frequency of cases in which death from tuberculosis was attributed to some other cause; and if all forms of the disease were accurately diagnosed, the mortality would probably exceed the figures given. There is no immunity in the human race. Certain individuals may appear to be more or less susceptible than others, but the question of greater or less exposure to infection cannot be ruled out. Differences in susceptibility could be determined only by inoculation with the same amount of the same culture. There are of course great differences in the race susceptibility in animals, but the general result of experiments has been to show that susceptibility of individuals of a species of the same age and under the same conditions is about the same. No human race is exempt, and the susceptibility in all is about the same, the relative frequency of the disease being governed mainly by the greater or less chance of infection given by the conditions of life. There may be a difference in the susceptibility of the tissues of the body due to local conditions, which may favor the reception of the organisms. There may also be conditions brought about in various ways which may favor the multiplication of the bacilli when once established. It seems to be a general rule that the young of all species are more susceptible than adults. It is evident from the usual localization of the disease in man and the opportunities which the bacilli have for leaving the body that every individual with tuberculosis is a focus of infection, more or less dangerous according to the locality of the tissues affected and the extent of the lesions. This being so, density of the population and the greater opportunities which this gives for disseminating the bacilli, are the principal factors influencing the frequency of the disease. The disease exists independently of conditions of climate or soil. Wherever the population is dense the disease is frequent; wherever there is a scarce rural population the disease is more rare, and this whether the locality is in the east or west, north or south, whether the altitude be high or low, whether the climate be dry or moist, hot or cold. The disease is rare in high altitudes, but if one compares the tuberculosis curve with the curve representing density of population it is seen that the infrequency is due not to altitude, but to scarcity of population. The increase in tuberculosis in civilized life corresponds with the irresistible movement of the population to the cities, and the substitution of sedentary indoor professions for agricultural occupations in the open air. Paris gives a general mortality from tuberculosis of nearly 5 per 1,000, and from this there is a gradual decline according to density of population to 1.81 per 1,000 in some of the country districts. Density of population means indoor life and factories. These undoubtedly increase the danger of infection because the bacilli in the sputum and discharged in the expiration spray are not exposed to the killing influence of sunlight. Whether crowded conditions and indoor occupations apart from increasing opportunity for infection have any influence on morbidity is uncertain. They probably have an influence on mortality. The frequency of the disease is influenced by the different professions, and this to some extent independently of density of population. Tailors give a high mortality, which may be due in part to the fact that this pursuit is not undertaken by the more robust. The disease is particularly common among those exposed to the dust coming from vegetable and mineral substances. The mortality in Switzerland from stone-cutters is 10.47 per 1,000. It is also high in those subjected to metallic dust, as in the grinders. The cause of this is probably due to opportunities for infection combined with the creation of local conditions in the lungs favoring the lodgment of the bacilli. An exception to this is given in the coal miners in England, who have a low mortality from the disease, notwithstanding the fact that their life in the mines is not under conditions which we ordinarily regard as hygienic. Cornet explains this by the fact that in the mines there is no opportunity for infection, the sputum not becoming dried into dust. In Switzerland the mortality in agricultural laborers is 2.10 per 1,000, railroad employees 1.84, foresters 1.75, locksmiths 7.2, printers and lithographers 5.55, watchmakers 5.19, coopers 5.8, bakers 5.6, tailors 4.90. In Italy there is the high mortality of 4.59 in students and seminarists. Pastors in mountain villages seem to have the lowest death rate from the disease.

When we consider the actual frequency of the disease, as shown by the presence of anatomical lesions which could have been produced only by the action of the bacilli, the figures are colossal. Every pathologist is aware of the frequency of caseous foci in lymph nodes, of cicatrices, nodules or indurations in the lungs, of adhesions between the pleuræ, etc., the greater part of which certainly must be attributed to tuberculosis. In the Boston City Hospital, to which patients with advanced tuberculosis are not admitted, such lesions are found in the ordinary conduct of the autopsy in about one-third of all cases. Where the determining of tuberculous lesions is especially held in view in making the autopsy, and where microscopic examination of organs and animal inoculation are resorted to for diagnosis of obscure lesions, the proportion of cases is much greater. The inoculation of animals with bronchial nodes coming from subjects presenting no macroscopic evidences of the disease has shown that the bacilli may be present without any or certainly without easily recognized lesions. I have shortly had the opportunity to examine the lymph nodes from a cow which seemed both on macroscopic and on cursory microscopic examination to be intact, but a more careful examination showed a few giant cells containing bacilli with scattered epithelioid cells around them and without any caseation. The most carefully carried out investigations on the frequency of anatomical lesions in tuberculosis are those of Naegeli made on 500 autopsies

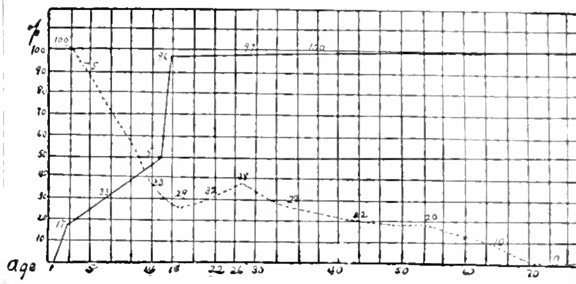

FIG. 4808.—Table taken from Naegeli, *Virch. Arch.*, vol. clx. The black line shows the frequency of anatomical evidences of tuberculosis at different ages; the dotted line, the cases in which the disease proved fatal.

(Fig. 4804). The curve shows the frequency of tuberculous lesions at different ages, reaching at eighteen the astonishing number of 97 per cent. Naegeli regards it as probable that every individual over forty has or has had at some time in his life an infection with tuberculosis. He shows that the infection increases irregularly up to 50 per cent. at fifteen years, and from that there is a rapid rise to 96 per cent. at eighteen. The dotted curve gives the percentage of fatal tuberculosis at the different ages, showing that all cases were fatal up to two and a half years, and from that a gradual decline to 29 per cent. of fatal cases at twenty in spite of 97 per cent. of infection. He argues from this that there is a special disposition in children to the extension of the disease, so that cases of infection are usually followed by generalization and death. This disposition decreases until the age of seventy, when there is practically no mortality in spite of universal infection. The figures with regard to children are misleading, and show that his autopsy material of children did not embrace the acute infectious diseases of children, and are not representative of average autopsies on children. Autopsies on diphtheria cases show a very high percentage of latent tuberculosis in children, and many of the old lesions met with in adults can be referred to infection in childhood. The percentage of lesions must, however, increase with age, for the reason that the longer a soldier remains in battle, the greater the danger of a wound. Tuberculosis was found in 35 out of 220 autopsies on diphtheria at the Boston City Hospital, or in 16 per cent. All but 21 of the 220 cases were under ten years of age. The examinations were not made with special reference to tuberculosis, and it is probable that many slight lesions which could be referred to this were overlooked. In 3 cases miliary tubercles were found only on the routine microscopic examination of the organ, there being no macroscopic evidence of the disease. In 3 cases there was healed tuberculosis of the lungs without lesions elsewhere. Contrary to general statistics which show the greatest frequency of the infection in the bronchial lymph nodes, the mesenteric lymph nodes in our cases were most frequently affected. In 7 cases the only lesions of the disease were found in these. In only 6 out of the 18 cases in which the nodes were affected was there intestinal ulceration. In but few of the cases were there any clinical manifestations of the disease, and in most cases the character of the lesions was not such as would have given rise to symptoms. Other statistics derived from diphtheria autopsies show about the same percentage of tuberculosis. Berliner in Freiburg found 19 cases in 107 autopsies on diphtheria, or 17 per cent. The tuberculous lesions were usually old, and as a rule were

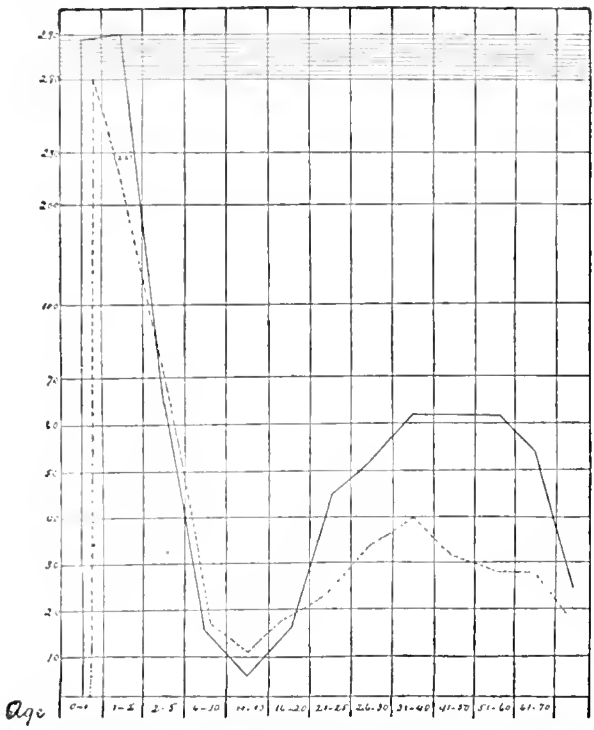

FIG. 4805.—Table of Holste, showing the Death Rate from Tuberculosis in Helsingfors for 1882–1889 for 10,000 inhabitants. The black line represents males, the dotted line females. During this period the death rate from tuberculosis was, for males 5.7 per thousand; for females, 3.8 per thousand.

not influenced by the diphtheria. Cohans in an analysis of 45 cases in Kiel found 95 cases, or 20 per cent. Nearly one-half of his cases could be regarded as definitely healed. The smallest percentage (13.3) was found by Crenemeyer in 459 cases of diphtheria. It is probable that these figures give a fair estimate of the frequency of tuberculosis in children. It is, if anything, too low, because in none of these statistics was any special examination made to determine the presence of tuberculosis; and children who were actually ill of the disease would not be so liable from their surrounding conditions to infection from diphtheria. No fault can be found with Naegeli's methods of estimating the tuberculous character of old lesions. They show in man a high disposition for infection, and a relatively slight disposition for the infection to extend and lead to death (Fig. 4805).

This latent tuberculosis, to which the term healed is often erroneously applied, is of great importance. We can regard a lesion as healed only when the cause which produced it is also destroyed and the lesion is no longer a source of danger for the body. The bacilli in these lesions are not destroyed; they can often be detected on microscopical examination, or, still better, by animal inoculation. They remain a fertile source of future, and often fatal, outbreaks of the disease. Even those which macroscopically appear to be healed may show the contrary on microscopic examination. I once examined a small caseous nodule in the apex of the lung of a young man who died from an accident, and who was apparently in a condition of perfect health. The caseous nodule contained bacilli, and around it were a number of miliary nodules in the cicatricial tissue, each with bacilli. Nothing shows the important part which latent tuberculosis plays more strikingly than the statistics of prison tuberculosis. All who have studied the question have been struck with the high mortality from tuberculosis, reaching in some cases up to seventy-five per cent. of all deaths. It is rare that it comes below fifty per cent. At first this was attributed to greater opportunities for infection in prison life. But this cannot be shown to be the case. The prisoners are generally under better hygienic relations, certainly as regards air and cleanliness, than they would be outside. Investigations of prison dust have not shown bacilli at all, or not in numbers sufficient to explain prison mortality by infection. Moreover, the mortality is greater during the first three years of prison life, and this is too short a time for death to have followed a primary infection in the prison. The study of mortality in cellular prisons, where each prisoner is separately confined and has no opportunity for infection from his fellows, shows about the same mortality as when they live in common. The attempt has also been made to explain it, in part, by the assumption that prisoners as a class are apt to be tuberculous. But the examination of those entering has not shown a percentage of tuberculosis much exceeding the average. The mortality can be explained only by the supposition that prisoners in common with other individuals of a like age have the disease in a latent form, and that the conditions of prison life favor the extension of the primary focus. It is a striking instance of the well-known fact of the influence of conditions of both body and mind on disease. Laënnec gives a striking example of the influence of external conditions on the mortality from the disease. In Paris he attended for six years the house of a religious order which had not the recognition of the religious authorities and was only tolerated. The inmates were depressed in spirits, their thoughts were always on the gloomy side of religion, and they were subjected to a rigorous discipline. The effect was the same on almost all. At the end of one or two months' sojourn the menses stopped and phthisis shortly appeared. In six years he saw two or three times almost complete destruction of the sisterhood, the exceptions being a small number composed of the superior, the door attendant, the sisters who had charge of the garden, and the cook. These were all persons who had more distractions than others, and whose work took them into the open air.

Infection.—The tubercle bacilli are the only source. The bacilli are obligate parasites. They probably never find natural external conditions favorable for their multiplication. They are not spore-producing organisms, and though more resistant than most vegetative forms of organisms, they can easily be destroyed by rational methods of disinfection. Exposure to sunlight destroys them. Individuals with the disease are the source of infection, and infection is in most cases at least confined to the immediate neighborhood of such individuals. The situation of the lesions of the disease particularly favors the extension of the infection. The lungs are chiefly attacked, and the sputum is the chief vehicle by which the bacilli are discharged. In advanced phthisis they are contained in the sputum in immense numbers. They may also be discharged from the body in the fæces in cases of intestinal tuberculosis, and by the bladder in genito-urinary tuberculosis. Tuberculosis of the skin rarely takes a form in which the bacilli are discharged to any extent. In the question of infection only the sputum need be considered. Individuals with the disease, except in the last stages, are not usually confined to rooms, but they mix with their fellows and carry the danger of infection with them. Infection can take place from the respiratory passage, from the alimentary canal, and from the skin. Infection from the respiratory passages is by far the most common. This is shown by the localization of the disease in the lungs and in the bronchial glands, in by far the majority of cases, and by other evidence.

An attempt has been made by some to deny or to minimize infection by inhalation. The bacilli discharged in the sputum when this becomes dry may enter into the dust. Those discharged in the open by the sputum may be disregarded. They are destroyed by sunlight and other conditions in the open. They are not present, or at least not present in a living condition, in the dust of the street. In close spaces (rooms) they have been found in the dust when the rooms were occupied by tuberculous patients. Sputum containing tubercle bacilli has been dried on pieces of carpet, and guinea-pigs have been caused to inspire the dust which came from beating the carpet, with positive results. Strauss has found bacilli in the nose of healthy individuals, by mopping out the nose with pledgets of cotton, washing this out in bouillon and injecting guinea-pigs. Moeller found tubercle bacilli in his own nose after two hours in the consultation room. Flügge thinks that it is not the bacilli in the dried sputum, and which may enter into the formation of dust, which convey the disease, but small particles of fluid containing the bacilli which are projected into the air in the act of coughing and even speaking, and which may remain for some time suspended in the air. Moeller suspended cover-slips in the vicinity of tuberculous patients, and found bacilli on them carried there by spray particles. He thinks the sputa containing the bacilli are with difficulty broken up into dust when dried. The infectiousness of the bacilli contained in the spray he showed by placing guinea-pigs in the rooms with tuberculous patients and having them cough into the cages. Several of the guinea-pigs became infected in this way. Flies may also convey the bacilli from the sputum either by carrying particles containing bacilli to food, or by their excreta. There would seem to be no question that the infection can be extended by inhaling either dust or spray particles, but there is little chance for this mode of infection to occur in the open except in the immediate vicinity of a case of pulmonary tuberculosis. Pigmentation of the lungs by carbon shows that solid particles can be carried into every part of the lungs. The expired breath in calm respiration is free from bacilli. It has also been shown that the bacilli retain a close connection with the sputum which comes from the lungs. The saliva has been found in most cases to be free even when the lung expectoration contains numbers of bacilli. Kitasato has also shown that a large proportion of those contained in the sputum are dead.

There has been considerable opposition to this idea of infection by inhalation. Those opposing have based their belief on the examination of healthy lungs of animals which, it has been asserted, are free from organisms; also on the seeming impossibility of causing solid particles to be carried by air currents along complicated systems of tubes representing the bronchi. The best series of investigations, however, have shown that the lungs of healthy animals may contain organisms. That none was found is by no means proof that the animal had not inhaled them, for they may be taken into the lymphatics and removed from the lung with great rapidity. After injecting the blood into the trachea of an animal it is scarcely possible to kill it quickly enough to prevent the corpuscles from passing from the lung into the bronchial glands. Neninger found that B. prodigiosus was carried into the lungs by the inhalation of spray containing the organisms; also, when the organisms were placed in the mouth and the animal caused to make forcible inspirations, they were found in the lungs.

Infection by dust and sputum particles need not take place solely by inhalation. Articles placed in the mouth or food may become contaminated and infection take place by the alimentary canal. Primary tuberculosis of the tonsils, which is not infrequent, and tuberculosis of the cervical lymph nodes are to be referred to infection from the mouth or pharynx. It is not necessary to assume that every case of primary tuberculosis of the intestine and the mesenteric nodes is due to the tubercle bacilli contained in milk. Bacilli may be taken into the digestive tract in many other ways than in milk. Infection by the intestinal canal, even secondary, is not very common in view of the possibilities. We often find no intestinal lesions in cases of advanced phthisis, notwithstanding the enormous numbers of bacilli which are swallowed with the sputum.

There have been a number of cases reported of infection by the skin. Most of these have been in connection with circumcision, the practice being to suck the wound to stop the bleeding. Other cases have come from tattooing, the saliva of an individual with pulmonary tuberculosis having been used to moisten the pigments. Infection cannot take place by the intact skin even when bacilli are rubbed on the surface.

The most common form of skin infection is that given in the post-mortem wart, the tuberculosis verrucosa. There seems to be a strong local predisposition to this, which is probably due to some anatomical condition of the skin. Some individuals become infected while others under the same circumstances of exposure are exempt.

It is in most cases extremely difficult to say when and how infection takes place. It very often does not occur under conditions which would seem to be the most favorable. In the acute infectious diseases in many cases it is possible to trace definitely the infection. Tuberculosis is a disease of slow development. The infection, when it takes place, may lead only to a latent tuberculosis, which may become the active cause of the disease many years afterward. In the study of tuberculosis in families there are cases which show that one member of a family after another may be attacked, the disease becoming a house epidemic.

The study of marital tuberculosis has shown that infection may not take place under conditions seemingly the most favorable. Leudet has investigated the frequency of infection in 74 marriages where one individual was tuberculous. In 61 cases there was no infection. Of the 13 cases in which the survivor became tuberculous, in 6 of these the ancestors were tuberculous. In 112 cases of widows or widowers, the former partner having been tuberculous, only 7 had the disease. These cases, collected by Leudet, were from the better classes, in which the chances of infection were less. Delacour investigated 54 marriages, in which one individual was tuberculous. In only 4 cases did the survivor die of tuberculosis. The general result of all these inquiries is to show that in marital tuberculosis the female is more apt to be affected than the male. It is probable that the chances of infection in marriage have been somewhat over-estimated. The parties are separated for a greater part of the time, and the chances of infection would not be probably so great as in the case of a mother or of two sisters living in the same house. There are quite a number of cases in which an individual with chronic tuberculosis had communicated the disease to successive wives.

The influence of heredity in the extension of tuberculosis must be considered under two heads. On the one hand, there is a widespread belief that the disease itself is not inherited, but that the offspring of tuberculous individuals have tissues of a peculiar character, in that they offer a better soil for the development of the tubercle bacilli and the extension of the lesions. Some even go so far as to refer such a supposed inheritance to remote ancestors, and see this disposition to the disease affect entire families. This is a widespread belief, and one which it is difficult to prove or disprove, either statistically or experimentally. Experiments on animals give no basis for the belief. The young of tuberculous animals, if they have not undergone an intra-uterine infection, and if they be removed from sources of contagion, are no more susceptible than the young of healthy animals. It cannot be denied that children of parents with tuberculosis, as the children of parents weakened by any disease, are as a class weaker and have less general resistance than children of healthy parents, and when the infection is once established the disease may spread more rapidly in such cases. The disease is so common that if we consider the remote as well as the immediate ancestors as a source of such a predisposition, it is possible to find an inherited source in almost every case of tuberculosis. It is impossible to consider this supposed predisposition to the disease apart from the greater chances for the infection to which children, in families in which some one member is affected, are subjected. Even with the best of care as regards sputum, the surroundings of such individuals must become infected by the sputum spray. The infection of the child may not manifest itself for years; only a latent tuberculosis may develop and the disease afterward appears, giving a supposed example of inherited predisposition.

The other view is that there is an actual inheritance of the disease. True germinal inheritance due to infection of either male or female germinal cell need not be considered, and the inherited tuberculosis is really a congenital disease due to intra-uterine infection of the embryo or fœtus. This undoubtedly may take place, but all the evidence with regard to it tends to show its rarity. It has been demonstrated experimentally, the most important work being that of Gaertner. He inoculated white mice in the peritoneal cavity with tubercle bacilli and then had them fecundated. Mice are less susceptible to the disease than guinea-pigs, a slow form of tuberculosis being developed without any interference with function. The period of gestation is only three weeks, and two or three litters can be obtained before the mother dies of the disease, the later broods being obtained in an advanced stage of the disease in the parent. The skin and alimentary canal were removed from the fœtuses, the entire body was rubbed up in water and injected into the peritoneal cavity of guinea-pigs. Two or three fœtuses were used to inject a single animal. One hundred and sixteen fœtuses so obtained were injected into thirty-six guinea-pigs and two of these developed tuberculosis. This is not a large number when it is considered how favorable the conditions were for infection. He also inoculated canary birds, by way of the peritoneum. These laid nine eggs, which were used for the peritoneal inoculation of nine guinea-pigs, the result being that tuberculosis developed in two of the animals. Gaertner does not think that such experiments represent conditions analogous to those in man. Relatively enormous numbers of bacilli were placed in the peritoneal cavity, and infection of the eggs and young took place through the oviduct. He injected the bacilli into the blood of ten pregnant rabbits. These lived a variable time, and fifty-one young were obtained from them. He took from each fœtus the entire liver, the bronchial lymph nodes, the spleen, and other tissues and injected the whole into the peritoneum of guinea-pigs. Five out of the fifty-one became tuberculous. He also inoculated mice in the trachea with a single drop of culture. The inoculation produced tuberculous foci in the lungs, a large spleen, and a liver containing numbers of bacilli. Gaertner obtained from these mice seventy-four young, which were used for the inoculation of thirty-nine guinea-pigs, with positive results in seven.

A number of cases have been published in which congenital tuberculosis in both animals and man has been demonstrated. The first case was that of Johne, who found tuberculous lesions with bacilli in a new born calf. The bacilli have also been found in the tissues without any lesions. Schmorl and Birch-Hirschfeld investigated the placenta and fœtus from a woman who died of acute miliary tuberculosis in the seventh month of pregnancy. No tubercles were found in either placenta or fœtus. Bacilli were found in the placental sinuses, and animals inoculated with the tissues of the fœtus acquired the disease. Ouche and Chamberlain found both tubercles and bacilli in the placenta of a woman who had acute miliary tuberculosis, and who died shortly after the birth of the child. The child lived for twenty-six days and died of general tuberculosis. We may be warranted in assuming congenital infection in a considerable number of children who died of the disease in the first weeks or months of life, but such cases are rare. It is probable that infection of the fœtus can take place either from the blood or by means of the genital canal, and either the father or the mother may be the source of infection. Jani was the first to show the presence of tubercle bacilli in the testicles and seminal vesicles, and even in cases in which these organs were not the seat of the disease. His work has been confirmed by other investigators. Very few bacilli have been found. Experimentally it has not been possible to transmit the disease by coitus either to the mother or to the fœtus. Friedman successfully infected embryos by injecting the bacilli into the vagina immediately after coitus.

Baumgarten has been the most persistent advocate of the theory of congenital tuberculosis. He was led to advance the theory as an explanation of the rarity of spontaneous infection of laboratory animals when they are exposed to it, and from the difficulty of explaining the situation of many primary foci by the assumption of infection from without. Primary foci are undoubtedly found in bones and other situations, to which the bacilli could be carried only by the blood stream. He thinks the bacilli are transmitted to the fœtus or embryo by either parent. The bacilli enter into the blood and may be deposited in various organs or tissues. The fœtal tissues are an unfavorable soil for the growth of the bacilli and the development of the lesions. The bacilli may remain and the lesions slowly develop and remain quiescent for long periods, becoming cases of latent tuberculosis. He considers this to be the most obvious explanation for primary tuberculosis of the bones.

There is absolutely nothing in favor of Baumgarten's theory that congenital tuberculosis plays any considerable part. It undoubtedly occurs, but it leads not to a latent but to a rapidly generalized tuberculosis. There is no evidence to show that the tissues of the embryo or fœtus are an unfavorable soil for the growth of the bacilli. All statistics which have been collected on the presence of latent lesions have shown that these increase progressively up to adult life. There is no necessity for resorting to the congenital theory for the explanation of tuberculosis in bone or other places where the bacilli could be carried only by the blood current. It is comparatively rare that we find this localization of the disease without an older focus at some place in the body from which the bacilli in small number should have been carried into the blood and deposited in the bones or elsewhere. It is not even necessary to have an older focus. Bacilli may be taken into the circulation without any evidence of a local lesion where they enter the body. Most of these bacilli would be stopped in the filter of the lymph-nodes and develop lesions in these. Ribbert and others explain the frequency of pulmonary tuberculosis not as a primary disease of lungs due to inhalation, but as a secondary blood infection coming from primary lymph-node tuberculosis. Most of the bacilli would be stopped in the lymph nodes, but it is possible under certain conditions that a few of them might get through into the blood without the production of lesions, or of lesions which can be recognized macroscopically. One sees not infrequently tuberculous lesions in the lymph nodes which are apparent only on careful microscopic investigation. The relative frequency and gravity of tuberculosis up to five years of age are due to the greater opportunity of the young child for infection and the relative lack of resistance of its tissues to the bacilli.

The character of the lesions produced by the tubercle bacilli and the histogenesis of the cells entering into the lesions have been the subject of numerous investigations, and by leading men in pathology. Not only has the histology of the tubercle process been cleared up, but much light has been thrown on other infectious processes by the study of tubercles. We may divide the changes produced into two classes: in one, tissue proliferation is produced alone or predominates; and in the other, exudations, which differ only in their ultimate end from exudations produced by a variety of influences. The new formation of tissue which results from the proliferation can appear in the form of small isolated nodules, or of larger nodules composed of aggregations of the small, or as a diffuse formation of tissue of the same character as that composing the nodules. The most numerous cells, and often the only cells, are known as epithelioid cells. These are cells which vary somewhat in form and size, and have, as their name suggests, some similarity to epithelium. The protoplasm is clear or finely granular, the nucleus is vesicular, and usually oval or slightly incurved. Among these epithelioid cells there are larger cells with numerous vesicular nuclei. These giant cells vary in size and shape and in the number and arrangement of the nuclei. They may be round or irregular, with numerous protoplasmic processes extending out among the epithelioid cells. The nuclei are generally arranged around the periphery of the cell enclosing a central space free from nuclei, or the cell is elongated and the nuclei are arranged at either end. The giant cells may be found either at the centre of the nodule or at one side. They may be found singly, without any epithelioid cells about them. Outside of the epithelioid cells, and often among them, there are numbers of lymphoid cells. Between the lymphoid cells there is a fibrous-tissue reticulum, which may extend a short distance between the epithelioid cells, but which does not anastomose with the reticulum formed by the protoplasmic processes of the giant cells. The fibrous reticulum is continuous with the surrounding connective tissue. Such a structure as this is found only in the smallest and most recently formed tubercles. The best examples are found in the tubercles developing in fibrous or granulation tissue and in certain organs, as the liver. The diffuse tuberculous tissue is formed on surfaces under conditions in which ordinarily only granulation tissue would be formed. It is found in joints, at the bottom of tuberculous ulcers, on serous surfaces, and in the lungs. In this formation the general appearance is that of granulation tissue composed of various kinds of leucocytes, formed and forming connective tissue, and young blood-vessels. In this tissue the epithelioid cells with scattered giant cells are not sufficiently circumscribed to be regarded as tubercles. Occasionally such a structure is found only on the surface.

The histogenesis has been chiefly studied experimentally, by injecting tubercle bacilli either into the general circulation or into the vessels of single organs. The epithelioid cells have the same genesis as they have in granulation tissue, and the same marked property of phagocytosis. They are derived from the large mononuclear, homogeneous leucocytes of the blood, the macrophages of Metschnikoff, the epithelium of serous membranes and of certain organs as the lungs, from all varieties of lymphatic endothelium and from the endothelium of blood-vessels, and from connective-tissue cells. They differ from the epithelioid cells of granulation tissue in being somewhat larger and paler.

When the bacilli are injected into the circulation tubercles are formed about collections of them in capillaries. They may be primarily taken into polynuclear leucocytes at these places, but these leucocytes do not enter into the formation of the tubercle. The tubercle begins with the presence of the bacilli in the endothelial cells of the vessels, and the first cells are formed by endothelial proliferation followed by the proliferation of adjoining cells. In the tissues the close relation of the endothelium of blood-vessels cannot be so easily followed. Baumgarten from his studies of the histogenesis of the tubercle believes that all sorts of epithelium as well as the cells of mesodermic structures can form the cells of the tubercle. He supports his view by the presence of nuclear figures in the adjoining cells. The nuclear figures are found, however, around the formed, and not the forming tubercle, and represent regenerative proliferation. There are two views as to the histogenesis of the giant cells. Weigert has always defended the view that they are formed by a proliferation of nuclei of epithelioid cells, the cell being so injured by the bacilli that it stops short of complete division. Metschnikoff also believes they are formed by nuclear division in a single cell, but denies that this is a degenerative process. For him the giant cell is an active phagocyte and one of the means of defence in the struggle between the bacilli and the tissues. The other opinion regards them as formed by the union of single epithelioid cells. The formation of the tubercle and tuberculous tissue is due to the action of the tubercle bacilli themselves. Similar changes cannot be produced by the injection of chemical substances derived from the bacilli. Typical tubercles can be produced by the injection of dead tubercle bacilli. Conglomerate tubercles are formed by the diffusion of the tubercle bacilli into the tissue around a single focus. The bacilli may be carried into the tissue by lymph streams or by leucocytes or the epithelioid cells. Between the individual tubercles forming the nodule there are numbers of lymphoid cells. Around the tuberculous tissue there are changes of a non-specific character due to the presence of the tubercles.

More characteristic even than the structure of the tubercle is the degeneration of the cells composing it. The cells lose their shape, the nuclei disappear, and the centre of the tubercle becomes changed into an opaque, homogeneous mass which may contain nuclear detritus derived from the nuclei of the degenerated cells. This change (caseation) is due to the tubercle bacilli, probably to toxic substances formed by them. Prudden and Hodenpyl have shown that the injection of dead tubercle bacilli into the circulation will lead to the production of nodules similar in structure to ordinary tubercles, the only difference being that caseation does not take place in them. It has been held that the caseation of the tubercle is due to its non-vascularit , but the tubercle produced by the dead bacilli is equally devoid of vessels. The tubercle may not only undergo caseation, but other forms of degeneration. The cells may become converted into a perfectly homogeneous refractive hyaline mass, hyaline degeneration, or the connective-tissue formation may involve the entire structure, giving rise to the fibrous tubercle. Caseation is usually preceded by fatty degeneration of the cells. Fresh sections of tubercle show fine fat drops in the cells outside of the caseous centre, and even giant cells often show fat inside the row of nuclei. As the tubercle increases in size the degeneration extends until it may involve the surrounding tissue. The caseation varies in its extent and in the rapidity of its formation. It is usually more extensive in tuberculosis of lymph nodes than in any other tissue. Lymph nodes may become completely caseous, with little or no evidence of formation of tubercles or of tuberculous tissue within them. Tuberculosis of lymph nodes is usually secondary to a tuberculous focus in their territory of lymph supply. If the caseation is due to the active substances formed by the bacilli, it is evident that such substances can be brought to them from the affected territory as easily as can the bacilli. With the beginning of the caseation polynuclear leucocytes appear in numbers in the surrounding tissue and in the tubercle. The necrotic tissue of the tubercle attracts them as does other necrotic tissue. The number of bacilli in the tubercle varies greatly. They can always be found in young forming tubercles and often in considerable numbers; in the older formations, single bacilli only are found or they may not be demonstrable. They lie in the caseous centre or enclosed in the epithelioid or giant cells. They are more frequently found in the giant cells in animal than in human lesions. Occasionally they are found in the granulation tissue outside of the tubercle, lying between the lymphoid cells and without any specific reaction about them. It is not easy to explain why the tubercle once formed should not homogeneously increase in size by the continued formation of tissue in the periphery and continued central caseation. The large tubercles are never formed in this way, but increase by the coalescence of single centres. The larg solitary tubercles in the brain show centres of caseation with a tissue between them which finally becomes caseous without undergoing the specific change into tuberculous tissue. The large tubercles in bovine tuberculosis show a similar conglomerate structure. Even the diffuse formation of tuberculous tissue does not lead to the formation of large masses. A possible explanation might be that the tissue which lies just outside the caseation has acquired an immunity to the action of bacilli, and these might pass through it without exerting any influence, the tuberculous tissue being formed only where this immunizing influence is not felt. A somewhat different action of the bacilli is seen when numbers of them are distributed over a surface the cells of which can take part in the formation of the tubercle, as in the lung. When the bacilli are injected into the trachea the cells lining the alveoli proliferate and the alveoli become filled with large desquamated cells and giant cells.

A more important influence exerted by the bacilli is the production of exudations. The specific tissue changes are in themselves relatively unimportant; except in cases of acute miliary tuberculosis or in cases of tubercle formation in organs essential for life, the specific tissue lesions are rarely sufficient to destroy life. The bacilli can lead to the production of a serous, fibrinous, or purulent exudation. The formation of such exudations is almost inseparable from the action of the bacilli, and may predominate over the tissue formation. I have seen a case of acute miliary tuberculosis in a child, in which vast numbers of bacilli were found in the lesions and in the vessels without changes in the tissue around them, where the miliary foci in all the tissues really represented miliary foci of exudation. The tubercles, particularly in the liver and spleen, appeared as foci of fibrin. These exudations are seen particularly in organs whose structure permits a great multiplication of the bacilli, as in the lungs, where the bacilli can grow in the walls of a cavity, as on the surface of a culture tube. The ease with which exudation can take place in an organ like the lungs or in a serous cavity facilitates this action of the bacilli. They may be considered among the true pyogenic organisms. Experiments have shown that the subcutaneous injection of avian bacilli into an animal usually leads to the formation of an abscess. The distinctly pyogenic action seems to take place when great numbers of bacilli are present, and when they have little power for the production of those chemical substances which lead to caseation. I have seen small definite abscesses in the lung due to purulent exudation and liquefaction of tissue in which the polynuclear leucocytes were filled with tubercle bacilli. Neither the exudation nor the surrounding tissue showed any caseation. This suppuration must be distinguished from the formation of puriform material due to the liquefaction of caseous tissue and the mingling of the broken-down granular fatty mass in a serous fluid. This is seen in the contents of a psoas abscess, and in this the tubercle bacilli may not be demonstrable. In the meninges the bacilli lead to the formation of an exudation which is chiefly fibrinous, which contains various numbers of polynuclear and epithelioid cells, and which is difficult to distinguish from that of other forms of meningitis. The exudation undergoes caseation just as the tuberculous tissue does. It is difficult to avoid the conclusion that such an exudation may be due to the local action of the chemical products of the bacilli.

Tuberculous ulcers may be produced either in the skin or in the mucous membrane. They may be the result of an infection extending from the surface or taking place in the tissue beneath. The process of their formation is a simple one, and due to the formation of tubercles or tuberculous tissue, with subsequent caseation and liquefaction of the caseous tissue. The ulcer increases in size by the continued formation of foci and their subsequent softening. This gives to the base of the ulcer, which is usually undermined at the edges, an irregular, eroded aspect. As the lymphatics afford the easiest route for the diffusion of the bacilli in the tissue, the ulcer usually enlarges in the direction of the lymphatics. The tuberculous ulcers of the intestine tend to enlarge transversely to the axis, and girdle ulcers, extending completely around the intestine, may be produced.

From a single focus the tubercle bacilli may be carried to other parts of the same organ or throughout the body. The distribution can take place by means of the blood, by the lymphatics, or by natural channels which connect a tuberculous focus with other parts of the organ, as the bronchi in the lung, or with other parts of the body, as the intestine. These methods of distribution give rise to special forms of tuberculosis.

Distribution by Blood.—A few bacilli probably enter the blood in all cases. The lesions which are produced in the different organs are due to the character of the circulation, which in some organs peculiarly facilitates the deposit of insoluble substances suspended in the blood, and to the character of the tissue, which may or may not facilitate multiplication and action of the bacilli. A careful microscopic examination of the liver will show the presence of a few miliary tubercles in almost every case of tuberculosis. The circulation in the liver, giving an enormous capillary stream bed with slow movement of blood in the capillaries, facilitates deposit of suspended particles just as a large body of water facilitates sedimentation. Miliary tubercles are never found in voluntary muscles because the tissue offers unfavorable conditions for their development. There is no other way of explaining the presence of lesions in bones than by blood distribution. It is also possible that tubercle bacilli may enter into the blood without the production of a primary focus. How these few bacilli enter into the blood stream is a matter only of conjecture. In most cases they probably come from a tuberculous lymph node, and in these the lesions may be so slight as to elude observation. When the tubercle bacilli enter into the blood in larger numbers they may be deposited in single organs, determined by conditions of the circulation, or they may be generally distributed, producing general miliary tuberculosis. In this, careful examination of the body will almost invariably show the source of the bacilli either in a tuberculous focus in a blood-vessel or in a tuberculosis of the thoracic duct. The exceptions to this are so few that we are warranted in believing that such a source existed but escaped detection. The tuberculosis of the vessel can result either from the infection of the intima or from the extension into the vessel of a tuberculous focus adjoining it. The former is the more common. In both forms the tuberculosis appears as a thrombus formation. A slow thrombus formation takes place at the point of infection, and in the thrombus the tubercle bacilli grow as in a culture medium. The vessel may be completely occluded, but generally the lumen is open and the thrombus may be partially covered by the endothelium. Such thrombi are most frequently found in the pulmonary veins, and may extend a considerable distance, two or more centimetres, along the wall. They may be distinguished from ordinary thrombi by their opaque white appearance. Microscopic examination of the thrombus shows a finely granular or homogeneous mass, denser in places, not unlike ordinary caseation. In tuberculosis of the thoracic duct the infection can also take place from the intima or by the extension of an adjoining focus into the duct. The duct may be converted into a solid caseous cord, or the lesion may be mural. To the theory of general blood infection by such foci various objections have been raised. Sections of the thrombus may contain very few bacilli, and it may appear so firm that apparently the bacilli contained in it have no opportunity to enter the blood. It is true that sections of the thrombi rarely show large numbers of bacilli in immediate contact with the blood stream. The bacilli were always present in the cases examined by me, and in some cases there were great numbers of them. To show the absence of connection between the bacilli in the thrombus and the blood stream, it would be necessary to examine all parts of it by serial sections. Moreover, it is only necessary for the focus to have been a source of infection; it need not be one at the time the autopsy is performed. We often find all the tubercles at about the same stage of development, showing that the mass of bacilli producing the lesions have entered the blood some weeks previous to the autopsy. The source of the bacilli may be a very unusual condition. In one case of extremely acute miliary tuberculosis in an adult the only old lesion apparent on first examination was a small caseous focus in the apex of the lung, which seemed to be entirely healed. A closer examination of the veins of the lungs and of other parts showed no source of the bacilli in them. On the examination of the aorta a few miliary tubercles were found at a point forming a line leading up to a small opening in the aorta which was at first considered to be the mouth of an intercostal artery. On slitting this up it was found to be a minute aneurism of the vessel, which was filled with a caseous mass more or less broken down and containing great numbers of bacilli. The aneurism was the result of an infection of the adventitia of the artery, the caseous degeneration extending from this up through the media, which had given way before it. The intima extended a short distance into the aneurism. Although it may not be possible to find the source of the bacilli in a vessel or in the thoracic duct, I have never seen a case in which such lesions were not associated with miliary tuberculosis. The source is not only shown in this way, but it is also evident from a careful examination of the tubercles themselves, which will very often be found in relation to the vessels. The miliary tubercles are never formed in certain places, and are but rarely found in others. They are never found in the voluntary muscles, nor in the skin. It is very rare also that any are found in the mucous membranes. Even in the mucous membranes of the alimentary canal, which is so liable to infection from the lumen, we but rarely find any eruption of the nodules. Whether there is any multiplication of the bacilli in the blood in these cases is uncertain, although one occasionally finds cases in which from the number of bacilli this conclusion seems almost inevitable. I have seen such a case in a child in which great numbers of bacilli were found in the capillaries of the liver, both free and enclosed in epithelioid cells, either within or attached to the wall of the vessel. In another case almost an injection of the capillaries with bacilli was found in the liver of a cat. Cases of chronic miliary tuberculosis are seen in which the tubercles are larger and more advanced in caseation. It is usually considered in these cases that small numbers of the bacilli are constantly entering into the blood stream. It is possible that an advanced tuberculosis of a lymph node may give the necessary condition without our being able to follow the bacilli through the sinuses and into the blood stream. When the disease has once been established, the number of bacilli in the blood may be added to by their multiplication in the numerous miliary tubercles in the walls of the vessels.

It is a rule without exception that, wherever the seat of the tuberculous lesions may be, the lymph nodes which receive the lymphatics from the affected regions are tuberculous. In the tuberculous tissue the bacilli are in close relation to the cell spaces and the lymphatics of the tissue. They are carried to the lymph nodes by the lymphatics, either free or enclosed in cells. The lymphatic vessels may be affected and converted into white cords filled with caseous material containing bacilli, or tubercles may be formed within them. Such a lymphangitis is often seen in the lymphatics extending from a tuberculous ulcer of the intestine to the mesenteric nodes. The nodes form a barrier to blood infection; they retain the bacilli in their sinuses. This barrier ceases to be when the node itself is infected, and tubercles develop in the tissue of the sinuses, from which bacilli pass into the blood. Miliary tubercles are formed in the nodes, either in the sinuses or in the follicles. The entire node may be almost filled up with typical miliary tubercles or by the formation of diffuse tuberculous tissue. In other cases we find the nodes enlarged, partly or wholly caseous, and without any evidence of specific tissue formation. Such a process seems very similar to the caseous pneumonia in the lungs. Few or no bacilli may be found in the caseous tissue, and it seems most probable that the caseation is due not to the action of the few bacilli *in loco*, but to the action of toxins which are formed by the disease in the lymphatic territory, and which are carried to the node and continuously act upon it. The lymphatics also play an important part in the distribution of the bacilli around the focus of infection. The infection of tissue leading to the formation of a conglomerate tubercle takes place by means of the lymphatics. Careful examination of the lungs in tuberculosis will often show tubercles or caseous tuberculous tissue in both the periarterial and the interlobular lymphatics. The infection of the large serous cavities of the body, particularly of the pleura, which is so often the apparent primary focus of the disease, takes place by means of lymphatics. The interlobular lymphatics of the lung pass to the pleura, entering into the subpleural lymphatics, which communicate with the pleural cavity. Tubercle bacilli can enter these lymphatics either without producing any lesion, in the same way that the dust particles can enter the lymphatics, or the lymphatic and pleural infection can be secondary to an inconspicuous primary lesion in the lung. The tuberculous infection can extend just as carcinoma often does in a direction opposite to that of the usual lymph current. There are innumerable anastomoses, and the direction of current may be changed by occlusion of certain vessels.

No other way of extension has the same importance as that along natural canals. These offer the readiest means not only for an extension of the disease in the organ affected, but also for carrying it to other organs. The bacilli find good opportunities for growth in these canals. In tuberculosis of the kidney we may find tubercles containing great numbers of bacilli which are growing in the peculiar spindle-shaped masses which are found at the edges of pure cultures.

All these modes of extension and the interrelation of all tuberculous processes can be studied to better advantage in the lung than in any other organ. I shall give a short account of tuberculosis of the lungs, as the disease here is most important both clinically and pathologically. In other organs the study of the lesions is much simpler. The lungs may be primarily or secondarily infected. Infection takes place by means of the bronchi or blood-vessels. The lymphatics play only a minor part in the extension of the disease in the lungs. In no other organ of the body does exudation become so prominent a part of the lesions. It is difficult to separate clearly the lesions produced by blood infection from the infection coming from the bronchi. The blood infection leads to the formation of miliary tubercles, starting in the interalveolar septa and in the other interstitial tissue of the lung. The epithelium of the alveoli takes part in the formation of the miliary tubercle, and bacilli are contained not only in the tissue but in the interior of the alveoli as well. With the entrance of the bacilli into the alveoli the conditions making bronchial infection possible are given. Exudation also takes part in the process, and fibrinous, serous, or hemorrhagic exudation may be found in the surrounding alveoli. This condition is more often found, and to a greater extent, in children than in adults, and it may be impossible to distinguish miliary tubercles coming from blood infection from miliary foci of tuberculous pneumonia coming from bronchial infection. The infection by the bronchi is of infinitely greater importance than infection by the blood-vessels. The primary infection of the lungs takes place in most instances by inhalation, the bacilli in the dust or in the spray reaching the tissue by the bronchi. This is shown by the predominating situation in the apices of the lungs. A great many reasons have been given in explanation of this, without any of them being satisfactory. So far as can be determined by the situation of other lesions due to solid substances conveyed by the blood-vessels into the lung, this situation of the primary lesions in the apices does not speak in favor of blood infection. The tubercles in miliary tuberculosis are more numerous in the lower lobes of the lung, and abscesses and infarctions are also more apt to be found in other places than in the apices. There can be no doubt that the primary infection may be hæmatogenous, and the primary lesions are frequently found in other parts of the lung than in the apices. It is rarely possible to see the early stages of a primary tuberculous lung. We frequently find either an old caseous focus with cicatricial tissue around it, or a focus of slaty induration with radiate cicatrices extending into the tissue; or, rarely, in cases of death from intercurrent disease we may find an earlier condition. I once found in the apex of the right lung of a young man a single focus of tuberculous pneumonia 0.5 cm. in diameter, which differed in no respect from the foci which are so common in advanced tuberculosis, and which must be referred to bronchial infection. Microscopic examination in most cases enables us to determine the character of the old lesions, and one certainly gets the impression that they are pneumonic in character.

It is rare that we find lesions that can be regarded as definitely healed. Around the old caseous foci single tubercles will be found outside of the cicatricial tissue showing a slow infection, probably by means of the lymphatics. In the cicatricial tissue we shall generally find fibrous tubercles which still show some remains of specific structure, or their situation may be shown by calcareous or hyaline foci. Probably in most cases the primary infection is followed by a period of quiescence, in which the process is slow or arrested. The bacilli increase in number, and infection of the surrounding tissue through the lymphatics and bronchi takes place, leading to new foci, which become united into a single caseous mass by the advance of the caseation in the primary focus. There is usually no marked advance of the process until the softening of the caseous tissue gives opportunity for an extensive general infection by the bronchi. There is still much uncertainty as to the immediate cause of the softening. It may be the result of the formation, in the caseous tissue, of a ferment which liquefies it in the same way that the liquefaction of the exudation in lobar pneumonia is brought about. Or it may be due to the action of other bacteria. The softening takes place either in the middle of the focus, or in one or several places, or at the edge, a line of softening separating the caseous mass. I have seen such softening take place both in the lymph nodes and in the lung. In one case there was complete sequestration of a caseous mass as large as a lemon, which lay in a cavity filled with thin purulent material. All around the edge of both the sequestrum and the lung there were great numbers of both tubercle bacilli and streptococci. With the expulsion of the softened mass there remains a cavity in the tissue. The cavity is usually surrounded by a zone of granulation and cicatricial tissue, in which numerous tubercles are found. The extent of cicatricial-tissue formation indicates the rapidity or slowness of the local extension. The interior of the wall may be covered by a layer of caseous tissue of varying extent, or it may have the soft velvety character of the wall of a chronic abscess. Tubercle bacilli are often found growing in masses in the wall with the same form of growth as in a pure culture in a test tube.

The further infection of the lung by means of tubercle bacilli or their products, carried into other parts of the lung by way of the bronchi, gives rise to several forms of the disease.

Tuberculous Bronchopneumonia.—This is due to the action of the bacilli. The foci of the disease are very similar in their situation and extent to the foci of bronchopneumonia met with in the infectious diseases of children, and due chiefly to streptococci. As in the case of the latter disease tuberculous bronchopneumonia has a relation to Miller's lobule of the lung. The infection begins at the bronchial termination in the atrium, and from this extends into the air sacs and air cells. Macroscopically, these foci have the appearance of miliary tubercles. Microscopically, the bronchial passage, the atrium, and parts of the air sacs contain leucocytes, often a small amount of fibrin, and large epithelioid cells. Some caseation of the contents is always found, but it need not be extensive. We may find the infection taking place not at the entrance of the bronchus, but at the bottom. At this point, however, the tubercles can scarcely be distinguished from those arising from blood infection.

Tuberculous Bronchitis.—Either in connection with bronchopneumonia or independently of it there may be an infection of the wall of a bronchus, due either to infection from within or to the extension into the bronchus of a tuberculous focus in the adjoining air cells, just as in the case of the tuberculosis of the vessels. The bronchus at this point loses its epithelium wholly or entirely; it becomes filled with an exudation which later becomes caseous. On section it appears as a round area of caseation more or less separated from the wall, or extending somewhat into the wall.

Tuberculous Pneumonia.—This is by far the most important of all the processes, and has always been recognized as such. The tuberculous infiltration of Laënnec was really a tuberculous pneumonia. The tuberculous pneumonia has more or less resemblance to foci of ordinary bronchiogenic pneumona. It may affect at the same time a large area of the lung, or the large areas may be produced by the confluence of smaller areas. The lung varies in macroscopic appearance. In some cases it has a gelatinous, almost transparent, appearance, with scattered small and opaque areas within it; or it may have the granular appearance of lobar pneumonia, but it is usually more opaque; or it may have on section a homogeneous, opaque character. Microscopically a great variety of conditions may be found. In the parts which present a gelatinous appearance we may find the alveoli filled with a homogeneous or slightly granular material in which are large numbers of epithelioid cells. In the process of hardening this material contracts and so leaves an interval between itself and the walls. This seems to be the result of a serous exudation, which has changed the character of the affected tissues, rendering them more dense than is commonly observed when they are infiltrated with ordinary serum. They present somewhat the appearance of an œdematous lung, but the material does not flow from the lung so easily on section, though it can be squeezed out to some extent by pressure. The walls of the alveoli may be but little changed. There is a varying degree of hyperæmia. The vessels may be distended with blood, but most of them may be empty. In most cases the alveolar tissue appears to be thinner than usual, or it may be infiltrated with cells. Shreds of fibrin may be found mixed with this material in the alveoli, or the fibrin may be so great in amount that the exudation can scarcely be distinguished from that of lobar pneumonia. In both the serous and the fibrinous exudations there is a varying number of polynuclear leucocytes. In some cases they may be so numerous that the exudation has a distinctly purulent character. These foci have often a close connection with the foci of bronchopneumonia and bronchitis. The number of tubercle bacilli in them varies. In the most recent foci, in which there is no softening of the caseous tissue, they may be absent entirely. In cases in which there is a close connection with foci of bronchopneumonia the tubercle bacilli may be found in the bronchopneumonic foci, and entirely absent in the diffuse exudation in the surrounding lung.

The etiology of this tubercuious pneumonia is not completely cleared up. It has been attributed to the immediate action of the tubercle bacilli, or to the influence of other bacteria, representing a mixed infection, or to the influence of products of bacilli. I am inclined to consider it due chiefly not to the bacilli, but to chemical products of bacilli. The tubercle bacilli growing in the walls of cavities must produce there a quantity of tuberculin. We do not know how much products from the advancing necrosis of tissue have to do with increasing the action of the tuberculin. In the advance of the process there is a considerable difference as compared with the extension of bronchopneumonias. Foci of bronchopneumonia do not extend by continuity of tissue, but by the continuous involvement of new bronchial territories. They are often sharply limited by the septa of the lung. In tuberculous pneumonia the process is never so sharply limited; the extension may be by continuity without any reference to bronchial territories. Cultures may show the presence of pyogenic organisms, and they possibly assist the process, but there is no reason whatever for assuming that such infections are primarily due to such organisms. Microscopic examination of the tissue fails to show them, or reveals their presence in very small numbers. We know that the tubercle bacilli are capable of producing these exudations. Exudations similar in character may be found in the meninges of the brain and elsewhere, without any suspicion being excited that their peculiar character is dependent upon the action of secondary invaders. The lesions differ from the ordinary pneumonia lesions chiefly in the changes which they undergo. Even if the action of other bacteria be assumed, the caseation which the tissue undergoes shows that the action of the tubercle bacilli predominates over any other action. Similar lesions cannot be produced by the injection of tuberculin into the lungs of a healthy animal; in animals, it is true, the conditions are different. The tuberculin when injected is rapidly absorbed, and produces generally toxic instead of local lesions. The material which acts here is in a state not capable of ready absorption, and must act locally. It represents the soluble products mixed with mucus, possibly with particles of tissue. In all cases it is in a condition which would not admit of rapid absorption by the lymphatics. I have repeatedly found in the accompanying bronchopneumonia great numbers of bacilli in the bronchi and none at all in the surrounding exudation. Caseation takes place first in the centres of these foci and advances. That the caseation is not due to an absence of vascularity is shown by the fact that it can take place in tissue which, so far as can be judged by the presence of blood in the vessels, still has a circulation, but how active it is, it is impossible to say. Softening takes place with more or less rapidity, and results in the formation of cavities of a different character from the primary cavities in the apices. These cavities are extremely irregular and represent large channels of softening. Their walls are often composed of the caseous pneumonia tissue without any demarcation whatever. Around the periphery of these foci there will usually be found some connective-tissue formation. This shows first as an organization of the process. Beautiful examples of organizing pneumonia may be found. There is a growth of connective tissue into the alveolar spaces, taking the place of the exudation. The connective-tissue formation may be widespread so that a section of a focus may show extensive organization taking place from the periphery and advancing toward the centre, which is represented by exceedingly irregular areas of caseation. When softening takes place, then the cavity will not represent a simple hollowing out in the pneumonic lung; but, however irregular the cavity may be, it will be bounded by cicatricial tissue. The distribution of the areas of pneumonia may be chiefly lobar. Single lobes of the lung are often found chiefly affected, and all parts of the lung are never found homogeneously affected. The infection is due probably not to masses of bacilli which come from the affected portions of the lung and flow on into other parts of the lung, but to spray particles of such material formed in coughing, these particles being formed chiefly, if not entirely, in the larger bronchi. The quick inspiration in violent efforts of coughing is particularly favorable for the injection of the material into the lung. There is always, in connection with these changes, emphysema in the surrounding lung—sometimes of a pronounced character.

Recently an attempt had been made to utilize the agglutination method in the diagnosis of tuberculosis, but up to the present time the success of this does not show it to be a method of practical importance. The agglutination only takes place in such low dilutions as to show its great uncertainty. It is possible that greater success may be attended by the use of certain strains of the bacilli which will agglutinate more rapidly than others.

TUBERCULOSIS, PULMONARY. See *Lungs, Diseases of: Tuberculosis.*

TUBERCULOSIS: SYMPTOMATOLOGY AND TREATMENT.—Symptomatology.—The general symptomatology of tuberculosis is practically that of all wasting diseases.

In the early history of the malady, often before it is possible to determine the point of its localization, there is a great loss of bodily strength; the patient loses in weight, perhaps even to the point of emaciation; the skin loses its natural color, growing pale; there is marked dyspnœa, due to the anæmia that exists, even though the respiratory organs be not involved; the pulse is habitually accelerated and feeble; the patient suffers from indigestion, either with anorexia, or having a good appetite which is gratified at the expense of subsequent suffering; and finally, sometimes not until later in the disease, there is fever, either constantly or during some part of the day. In addition to these general symptoms, the involvement of individual organs or parts, such as the lungs, the meninges, the peritoneum, the bones, or what not, gives rise to symptoms peculiar to the part involved.

These individual symptoms will be described in detail in the articles which are devoted to the consideration of the diseases of such organs or parts, and therefore need not here be specified. It may be profitable, however, briefly to review the different methods of invasion of the several organs, especially with reference to the presence or absence of the general symptoms enumerated above.

Pulmonary tuberculosis is the most common and the most familiar form of tuberculous disease. It occurs under one of three forms:

First—Acute pneumonic tuberculosis, the onset of which is sudden, with a chill, quickly rising temperature, the physical signs of lobar pneumonia, sputum which may resemble that of lobar pneumonia, but is likely also to reveal the presence of the tubercle bacillus. This form may end fatally, even as early as the second or third week, and is generally mistaken for a severe case of simple lobar pneumonia. The importance of a correct diagnosis may be of more value in protecting others from infection than in saving the life of the patient.

Second—Acute tuberculous bronchopneumonia. This form is more frequent in children, often following other infectious diseases, as measles or whooping cough. The onset may also be sudden, with repeated chills, very high temperature, and death within a few days. Or it may run on for weeks, or even months, terminating in chronic phthisis.

Third—Chronic pulmonary tuberculosis. Here the onset is more gradual and insidious, accompanied with the general symptoms of debility, emaciation, rapid pulse, dyspnœa, pallor, indigestion, and moderate fever during a part of the day, before the pulmonary symptoms are severe, and long before night-sweats or a pulmonary hemorrhage alarm even the unwary.

It goes without saying, that the reverse of this picture may also be seen, when an alarming hemorrhage is the first sign of trouble, or a persistent cough long precedes the more general symptoms.

Tuberculous meningitis occurs more frequently among children than among adults. The prodromal symptoms are loss of appetite, loss of weight, great peevishness and irritability, without fever or local symptoms, until gradually or very suddenly and violently the true meningeal manifestations appear.

Tuberculous peritonitis presents a very varied picture, as a rule showing none of the general symptoms of tuberculosis. It may be entirely unsuspected and has repeatedly been found to exist when the abdomen was opened for the relief of other conditions. It may appear suddenly, with fever, severe pain, and the ordinary symptoms of acute peritonitis. Or the onset may be gradual, with abdominal tenderness, tympanites, and a low grade of fever not unlike the beginning of typhoid fever.

Tuberculous Pleurisy.—The ordinary form of this disease is subacute or chronic in character. The onset is insidious, with no grave general symptoms, and even the local symptoms are so little marked that the diagnosis of a pleuritic effusion, which is usually sero-fibrinous, is often not made until it has existed for some time. Another form is that of *acute tuberculous suppurative pleurisy*. Of this, Professor Osler, in his "Principles and Practice of Medicine," says: "The fact is not so generally recognized that there is an acute, ulcerative, and suppurative disease which may run a very rapid course. The pleurisy sets in abruptly, with pain in the side, fever, cough, and sometimes with a chill. There may be nothing to suggest a tuberculous process, and the subject may have a fine physique and come of healthy stock."

Tuberculosis of the pericardium is not so common as that of other serous membranes. It has been found *post mortem* when nothing during life had led to a suspicion of its existence. In other cases it has been accompanied during life with the ordinary symptoms of cardiac insufficiency or cardiac dropsy.

Tuberculosis of the kidneys and of the genito-urinary tract, as a primary lesion, is not very uncommon. The disease of the kidney gives the ordinary symptoms of pyelitis, with the presence of tubercle bacilli in the urine. It may persist for years while yet the patient enjoys fair health and shows no other signs of tuberculosis.

Tuberculosis of the testis may also, apparently, be primary, although undoubtedly depending on the presence of some other tuberculous focus within the body. It is early associated with the general symptoms of tuberculosis and should not escape recognition.

Tuberculosis of the lymph glands (formerly called scrofula) is one of the most common of the tuberculous affections and the one most likely to result in a spontaneous cure. The cervical glands are the ones most frequently affected. The general symptoms of tuberculosis do not appear, or do so only to a very slight degree. Fever is absent unless the extension of the disease is rapid or suppuration takes place. When the mesenteric glands are involved (tabes mesenterica) nutrition is seriously interfered with and rapid emaciation ensues, with the characteristic enlarged and tympanitic abdomen, diarrhœa, etc.

No reference need here be made to tuberculosis of the larynx, pharynx, nasal cavity, intestinal canal, or other parts, the involvement of which is secondary to pulmonary or other forms of the disease.

Bone Tuberculosis.—With regard to the general symptoms of this form of disease we quote from Tillmann's "Text Book of Surgery": "The general health in tuberculosis of bone is very often but little, or not at all, affected. There is frequently a slight fever, varying with the extent of the process. It is a common occurrence to find that the general health is only slightly disturbed, even when extensive multiple tuberculosis is present. In general the fever is most pronounced before the tuberculous inflammation has extended beyond the bone, but it is usually slight and, as a rule, disappears more or less completely when the inflammation has worked its way to the surface of the body." . . . "Quite often it happens that for a long time symptoms peculiar to bone tuberculosis are absent; severe pain, especially, may long be missed, unless a neighboring joint, the periosteum, or overlying parts, are attacked by the tuberculous inflammation. Symptoms generally do not appear for months."

Acute miliary tuberculosis, of the general or typhoid form, is a disease in which the various organs of the body generally are invaded by the tubercle bacillus and filled with miliary tubercles. The patient presents the symptoms of a most profound infection with few local manifestations of a characteristic kind. After a brief period of general indisposition, not unlike the prodromal stage of typhoid fever, the patient enters on the febrile stage, his temperature quickly reaching a height of 102° to 104° F. One of the main characteristics of the fever is its irregularity, with perhaps a morning rise and an evening fall, or two crises during the day, with a fall below normal, but, as a rule, with no chill. Some cases are said to run their course to a fatal termination entirely without fever. Leucocytosis is usually present. Pulse and respiration are quite rapid. Pulmonary symptoms may appear. Jaundice is not infrequent. Coma usually terminates the scene. In very rare instances tubercle bacilli are found in the blood.

TREATMENT.—Even without treatment, in any strict sense of the term, the restoration to health of people who have suffered from tuberculosis is no very unusual occurrence. As a matter of course this is more likely to occur under favorable hygienic conditions, but it does also occur, at times, under very unfavorable conditions. Much as it has been sought, and often as its discovery has been claimed, there is as yet no specific for this malady. Very much, nevertheless, has been accomplished during the past twenty years in limiting the spread of the disease, in prolonging life, and in effecting cures. When Koch announced his discovery of the tubercle bacillus, and shortly afterward introduced his tuberculin treatment, great hopes were entertained that "the white plague" was to be banished from the earth. Great as our disappointment has been, it must still be confessed that Koch's discovery has placed in our hands the power, to a great degree, of limiting the spread of the plague, and of thus, at least, beginning its extermination.

Prophylactic or preventive treatment, therefore, offers to-day the greatest field for activity, and holds out the best promise for favorable results. This implies, in the first place, the furtherance of everything that contributes to good hygiene; the abolishment of crowded tenements for the poor; the admission of fresh air, and above all of sunlight, into living-rooms and working-rooms everywhere; the limitation and regulation of child-labor and of the hours of labor for old and young; food inspection; instruction in cooking; provision for bathing facilities, and a thousand things besides that go to make healthy living possible. Not only must this possibility be placed within their reach, but the ignorant must be instructed as to the importance of these measures for health and for life. All this and much more belongs to the department of public health in states and municipalities, aided by the efforts of benevolent organizations, supported by the voice of the public press, and ceaselessly agitated by the medical profession everywhere.

In order that the tuberculous, and especially the phthisical, patient may become as little as possible a menace to the health of those about him, such cases should in all municipalities be reported to the board of health, not for the purpose of subjecting them to annoying surveillance, but that they and their friends may be instructed in a few simple rules for the safety of those who are well. Furthermore, after the death of a phthisical patient the room which he has occupied should be thoroughly disinfected.

Patients and friends should be instructed as to the vital importance of the destruction of all sputa of a phthisical person. Such persons should never spit anywhere except into a receptacle containing a germicide solution or into cloths or pasteboard cups which are afterward to be burned. The phthisical patient should, if possible, sleep in a well-ventilated room by himself.

Children or young people who have shown any suspicious symptoms, or those who are suspected of a possible predisposition to tuberculosis, should be brought up, as much as possible, in the open air and the sunlight. They should be hardened against exposure by daily cold sponging, be warmly clothed and well fed, sleep with open windows, and avoid all crowded rooms. The first signs of nose or throat troubles should be vigorously treated. Even the trifling ailments of such subjects should be given attention, and during convalescence from serious illness they should be carefully watched.

In cities and towns, and even in many villages, much of the regulation of public hygiene above referred to belongs to the boards of health. Even here such regulations will fail of their legitimate end unless faithfully and actively supported by the medical profession. But in all rural districts the practising physician is the board of health, the sanitary inspector, the police officer, as well as the friendly counsellor of the family. When the entire medical profession in any land wakes up to the importance of the preventive treatment of tuberculosis, and takes the field in an active and relentless campaign against the spread of the disease, the results will be such as the greatest enthusiast has hardly dared to dream of.

In the treatment of tuberculous patients, where anything may be expected in the way of cure, or of the arrest of the symptoms, our main reliance, again, is on *good hygienic surroundings, proper and sufficient feeding, fresh air and out-of-door life*. By hygienic surroundings we mean absolute cleanliness, the avoidance of all dampness in dwellings, and the free admission of sunshine. The feeding problem is a hard one, since we have to do so often with people of small and capricious appetites. The diet should be simple, varied, and nutritious—milk, eggs, meats, cereals, breadstuffs, vegetables, with as much as possible of fats. Many patients who cannot eat very heartily at any one meal may gain in weight and in strength by eating six times a day—that is, by taking nourishment between meals in the shape of milk, broth, raw eggs, etc. As much of the daytime as possible should be spent out of doors, not in wearing one's self out by undue exercise, but much of the time by sitting or lying in the sunshine. Bedroom windows should be wide open at night, or, better yet, the patient, warmly bedded, should sleep out of doors, on a veranda, or on the roof, if need be, and if the roof happens to be flat. *No tuberculous patient ever died of out-door living, by day or by night, while thousands of lives have been saved by nothing else.*

Because of the difficulty of carrying out the methods above indicated in cities, or in regions where the climate is unfavorable to out-of-door living, we come to the question of the *climatic treatment* of tuberculosis, and of *sanatorium treatment*. Both of these subjects will be fully discussed, under their respective headings, by other writers in this HANDBOOK. Suffice it here to say that the best climate for the tuberculous patient is the one that furnishes pure, dry air, without excessive heat or dust, and the greatest number of days of sunshine during the year. If to this be added a more rarefied atmosphere, such as is found at an elevation of from three thousand to six thousand feet above sea level, and the conditions which supply a reasonable degree of comfort and good food, we have the ideal resort, at least for the consumptive. Such a climate and conditions are to be found notably in Colorado, in portions of New Mexico and Arizona, and in Western Texas.

Because of the extreme difficulty and often the impossibility of carrying out hygienic, dietetic, and other regulations while the patient remains at home, it might be expected that great advantage would accrue from the treatment of such patients at well-regulated sanatoria, whether private or public, and experience has proved that this expectation is realized. Even under unfavorable climatic conditions the results of sanatorium treatment have been most favorable, especially for that class of patients who cannot secure the best conditions at home. There is no charity that will so well pay the community for the capital invested as the establishment and maintenance of such institutions.

Medicinal Treatment.—As before stated, there is no specific treatment for tuberculosis. Tuberculin and all its modifications have, on the whole, proved failures. The same is true with regard to all the antitoxic serums and antiseptic injection preparations from which, one after the other, something has been hoped, but nothing realized. Medicated inhalations benefit a bronchitis, but never cure phthisis. Pneumatic cabinets have had their day. And so one might go on through a long list of disappointments.

Cod-liver-oil, that old stand-by, still does good where the stomach will tolerate it, and helps much in maintaining the general nutrition, which is a most vital point. It is undoubtedly of most marked value in bone and gland tuberculosis, especially in the young. It is best digested when administered in connection with malt extract.

Arsenic is the most valuable general tonic that can be given to the tuberculous, whether or not the claim holds true, which has been put forth by some, that it tends directly to make an unfavorable soil for the development of the bacillus.

Creosote and *guaiacol* have had the same claim advanced on their behalf, probably with no very good reason. It is not probable that any drug which is administered ever reaches the tissues in sufficient amount to modify their value as a culture ground for bacteria. But there is no denying the fact that these drugs lessen the amount of expectoration and relieve cough, without disturbing digestion or constipating the bowels, and so are a source of great comfort and benefit to the phthisical patient.

Iodine preparations are of undoubted value in gland tuberculosis. Lugol's solution, administered internally, iodide of potassium, or iodide of iron, are the forms most commonly used.

Surgical interference at certain stages of glandular involvement and in bone tuberculosis is imperative, and will be treated of elsewhere. Of late years operative procedures, in bone and joint tuberculosis, have been largely superseded by injections with or applications of *iodoform emulsion*, with most admirable results. In these cases iodoform seems to hav :a direct anti-tuberculous action. It is not too much to hope that before long similar injections into tuberculous lung cavities or areas may yield better results than they have in the past.

Details with regard to the treatment of individual symptoms of pulmonary or other forms of tuberculosis, however, do not belong to this article and will be given elsewhere. The general principles laid down above are applicable to all forms of the disease. It has been within the experience of the writer to see cases of tuberculosis of glands, of the urinary tract, and of the testis (the latter of which did not seem to have been arrested by operative removal), as well as of pulmonary tuberculosis, apparently cured by a change of climate, change in methods of living, good hygiene, and an outdoor life.

Edward W. Schauffler.

TUMENOL.—This compound, which is very similar to thiol, has also been proposed as a substitute for ichthyol. The mineral oils obtained by the fractional distillation of coal-tar are supposed to contain a class of unsaturated hydrocarbons, which are readily acted upon by sulphuric acid. These hydrocarbons, treated with concentrated sulphuric acid, constitute the active ingredients of tumenol. The hydrocarbons undergo sulphonation and are separated as a dark, thick liquid, containing sulphone and sulphonic acid, known as *commercial tumenol*. It is a dark brown, almost black fluid of a syrupy consistency, acid in reaction. *Tumenol-sulphone* and *tumenol-sulphonic acid* may be separated from the commercial tumenol by the addition of soda lye, which combines with the acid to form a soda salt. The tumenol-sulphone is a dark yellow, thick liquid. Tumenol-sulphonic acid is a dark powder having a peculiar, faintly bitter, taste. The therapeutic uses are the same as those of ichthyol and thiol. The commercial tumenol is that which is generally used. From this two forms of solution are prepared for use, one containing ten per cent. of tumenol in equal parts of ether and rectified spirit and water, and the other containing glycerin in the place of the water. It may also be used as an ointment. The tumenol sulphonic acid is employed as a powder, or in solutions, of the strength of one or two per cent. *Beaumont Small.*

TUMORS.—(Synonyms: Common synonymous terms are new growths, neoplasms, malignant disease, blastomata.)

DEFINITION.—It is difficult to give a clear, exact definition which will apply to the term *tumor* under all conditions, because the word, which etymologically simply means increase in size, has a clinical and a general as well as a strict anatomical use. For example, clinically, increase in the size of a part has been and is now designated as tumor, as when we say that the four classical symptoms of inflammation are rubor, calor, tumor, dolor.

The word is employed in a vague general way when we apply the term acute or chronic splenic tumor to a spleen which is enlarged in consequence of an acute or chronic inflammatory process.

In the narrow sense of the word a tumor may be defined as a more or less circumscribed new formation of tissue, for which no cause can be assigned, and which, either in its growth, or in its relations, or in the character of its elements, departs more or less from the type of the normal tissues of the body. It possesses independent or autonomous growth without physiological limitations and serves no physiological purpose.

Tumors approach on the one hand the processes of regeneration and repair, and, on the other, certain inflammatory processes (sometimes called infectious tumors), which are due to definite causes. They also stand in close relationship with certain embryonic displacements of tissue, malformations, and inclusions from which it is not always easy to distinguish them.

The principal difference between infectious tumors and true tumors is this: In a metastasis of an infectious tumor the parasite which has caused the new growth is carried elsewhere and incites the tissue where it lodges to the formation of new tissue, which resembles that in the primary growth: in the metastasis of a true tumor a cell or group of cells of the original tumor is carried elsewhere and by its own growth produces a secondary nodule which resembles the primary growth.

Tumors vary much in *size*, from microscopic nodules to masses weighing more than the body itself. They also vary greatly in *shape* because they are influenced by many conditions. A tumor growing in the interior of a solid organ, and growing equally on all sides, is round, but if it projects into a cavity, it usually adapts itself to the shape of that cavity if the latter is small enough to exert pressure. Tumors situated near the surface of an organ usually find less opposition to growth above the surface, and hence may project more or less above it, or even be connected with it only by a slender pedicle bearing blood-vessels. Tumors developing in the wall of the uterus remain there, or project into the peritoneal cavity or into the cavity of the uterus, according to their situation in the centre or near either surface of the wall.

The majority of the tumors are grayish to white in *color*, but many other colors, such as yellow, pink, red, brown, black, and green, are sometimes seen, and a few of them are fairly characteristic, as the green of the chloroma and the brown and black of the melanoma.

The *consistence* of tumors varies from the hardness of bone and the density of fibrous and myomatous tissue to the flabby toughness of the œdematous fibroma and the soft juiciness of a rapidly growing sarcoma.

Structure.—All simple tumors consist of two parts,—of the tumor cells, which may or may not secrete an intercellular substance, and of a stroma furnished by the tissue in which the tumor grows, in consequence of a physiological demand for nutrition and support made by the tumor cells. The stroma consists of blood-vessels which usually are accompanied by a varying number of connective-tissue cells and their intercellular substances. The blood-vessels are often of the simplest type, and in some tumors may consist of endothelium only.

A few examples will make this difference between tumor and stroma clear. In an adenoma or carcinoma the epithelial cells are the tumor cells; they alone are necessary to form metastases. All the cells of the connective-tissue stroma and of the blood-vessels present both in the original growth and in the metastases are intimately associated with the tumor cells, but they are furnished by the tissue in which the epithelial cells are proliferating. They do not invade surrounding tissues or give rise to metastases.

In a glioma the neuroglia cells, with their characteristically staining fibrillæ, can readily be separated from the stroma, *i.e.*, from the blood-vessels and accompanying connective tissue. But in many connective-tissue tumors, such as a fibrosarcoma, for example, it would be difficult to say whether certain cells along a blood-vessel were true tumor cells or only connective-tissue cells of the stroma. In a myoma it is impossible to say at present whether the reticulum that surrounds all of the muscle cells is the product of the connective-tissue cells of the stroma or of the smooth muscle, *i.e.*, tumor, cells themselves. The latter conception seems the more probable one.

In some tumors, such as carcinomata, the cells of the stroma often show such marked proliferative tendencies that their increase must be regarded—partly at least—as a reactive inflammatory rather than a simple physiological growth.

Growth.—Tumors start from a single cell or group of cells and grow by proliferation of those cells. They do not infect other cells and cause them to turn into tumor cells. In their growth they follow the same laws of cell proliferation that hold in normally growing or regenerating tissues. Hence in all rapidly growing tumors mitotic figures are very common, and the number of them present in a given tumor furnishes the best means of judging its rapidity of growth. Irregular and multiple mitotic figures are common, but are not characteristic of tumors, as it has been shown that they occur also in active regenerative processes.

A tumor has two modes of growth. In the one, which is called *interstitial expansive growth*, the tumor grows simply as a mass, pushing aside the tissues with which it comes in contact. Such tumors are very frequently surrounded by a sort of capsule of connective tissue which separates them from the surrounding tissue and through which pass the vessels of the tumor.

The other method of growth is by *infiltration*. In this case the tumor does not grow as a mass, but, probably because it finds better nutritive conditions or less resistance to growth in certain places, the cells of the tumor press into these places and infiltrate the surrounding tissue. In these cases a naked-eye examination cannot determine the limitation of the tumor; for a tissue which appears normal to the naked eye may be infiltrated with rapidly growing cells of the tumor.

The effect of tumors on the surrounding tissues is often to cause degenerative, inflammatory, and regenerative processes.

Metastases.—A tumor developing in a certain organ or tissue may remain solitary. In other cases a number of tumors of similar structure may develop later in other parts of the body. The tumor in the place of origin is called a primary tumor. The tumors in other parts of the body, which are derived from and develop in consequence of the primary tumor, are termed metastases. These metastases are due to cells or parts of the tumor being carried by the lymphatics or by the blood-vessels into other parts of the body, where they develop, forming tumors similar in character to the primary growth. It is not at all uncommon to find tumors growing into the vessels or lymphatics. They may fill up and grow along them, or the single cells may be carried in the current. Where these metastases take place will depend upon the blood and lymph circulation, and also to some extent on the tissue in which the cells lodge. If the tumor grows into a lymph vessel, then the cells will be carried into the lymph nodes connected with the part from which the tumor arises, and the metastases will develop in them. We have an example of this in carcinoma of the axillary lymph nodes following carcinoma of the breast; or in metastases in the pelvic lymph nodes following carcinoma of the uterus, etc. When the tumor cells enter into the blood, they are carried into the nearest capillary circulation, where they remain and develop metastases. Thus we have metastases in the lungs when the cells enter the systemic circulation; metastases in the liver when the cells enter the portal circulation. In case the tumor growth takes place in a large space, such as the pleural or peritoneal cavity, the cells of the tumor may get free and be carried to various places over the surface, giving rise by *implantation* to secondary tumors. This is seen often in tumors of the ovary, which may rupture into the peritoneal cavity and produce numerous small tumors over its surface. These secondary nodules, due to implantation, are also common secondary to carcinoma of the stomach. The cells are distributed by the movements of the intestine.

Recurrence of a tumor in the original site is due to incomplete removal of the primary tumor. This is sometimes due to the fact that the tumor is so situated that it is difficult to get at. A good example is offered by fibromata of the nasopharynx. If a tumor shells out easily, the surgeon is likely to think that he has the whole of it, when, as a matter of fact, the surrounding tissue may be invaded in various places.

The danger of recurrence, in the case of carcinoma, is so well known and feared that a generous margin of apparently normal tissues is always removed with the tumor.

Multiplicity.—Most tumors develop in but one situation in the body at once, but following this primary tumor there often are secondary new growths, due to metastases. Certain tumors, however, frequently are multiple and each nodule is independent of the other in its origin; for example, multiple myomata of the uterus and multiple fibromata of the skin. Less commonly lipomata and angiomata may be multiple. Tumors of the kidneys and ovaries are not infrequently bilateral in origin. Some tumors, such as the malignant lymphomata, spread so quickly that they seem to have a multiple origin, but probably do not.

Multiple tumors of different structure occurring at the same time in one individual are rare and must be regarded as accidental coincidences.

The *nutrition* of tumors takes place by means of blood-vessels which are developed from the blood-vessels of the part in which the tumor arises. The development of blood-vessels and the enlargement of the old blood-vessels from which the new ones arise take place according to the laws of nutrition. Wherever there are numbers of multiplying cells demanding greater nutrition new blood-vessels will develop to supply this demand.

In general the vessels of tumors have the same character as the normal vessels, but in certain of the sarcomata the blood-vessels are more irregular in character and may be represented by mere fissures lined with endothelial cells.

The vascular supply of a tumor is dependent largely on the rapidity of growth. A tumor which is growing rapidly has a much larger vascular supply than a tumor which is growing slowly.

A tumor is able to make greater demands for its nutrition than the normal tissues of the body. It is not at all uncommon to find rapidly growing tumors developing in people of advanced age in whom the general nutrition of the body is poor, and in whom the processes of regeneration and repair are at a low ebb. Tumors composed of fat tissue may develop and may grow in individuals in whom, owing to disease, the subcutaneous and other fat of the body has almost entirely disappeared. Conditions of malnutrition, which may influence the nutrition of all other tissues of the body, have no effect in retarding the growth of the tumor.

Phagocytosis.—The cells of some of the rapidly growing tumors are often phagocytic for other cells, particularly leucocytes. The partially digested remains of these cells lying within vacuoles in the protoplasm form inclusions of various shape and size which have often been mistaken for protozoa, especially in carcinomata.

In the malignant lymphoma many of the tumor cells are taken up and destroyed by the large endothelial cells lining the reticulum.

Various forms of *degeneration* are common in tumors. In consequence of the often extreme rapidity of growth of the cells the blood-vessels may become compressed, leading to fatty degeneration or necrosis. The veins passing out from a tumor may become constricted so that intense congestion and hemorrhage may occur in certain parts, or hemorrhage may follow the rupture of imperfectly developed vessels. The necrotic tissue in tumors has the same attraction for leucocytes as in normal tissues. Ulceration is not at all uncommon in tumors on the surface of the body, especially where they project more or less, and it almost invariably occurs in tumors involving mucous membranes. Invasion of tumors by suppurative and other bacteria is fairly common.

Certain tumors tend to produce in the body a state of marked malnutrition, which is termed cachexia. The cachexia may be accompanied by such definite forms of metamorphosis as the amyloid. This malnutrition is due to a number of causes. In the first place, it may be brought about by the presence of tumors in certain places where they will interfere actively with the general nutrition; for example, tumors may lead to stricture or to closure of the alimentary canal. Secondly, tumors by the products of their own degeneration, or by toxic products due to invasion by bacteria, may produce retrograde changes. Thirdly, pain, loss of sleep, and the anxiety produced by a malignant tumor will interfere with nutrition.

The *diagnosis* of a tumor cannot be made from isolated cells alone: there are no cells which are characteristic, for example, of carcinoma or of sarcoma. The diagnosis of a tumor depends on the arrangement of the cells of which it is composed with relation to each other.

The *classification* of tumors is a subject of much difficulty. This is due chiefly to three causes: to our lack of knowledge regarding their etiology, to the great diversity in their structure, and to the present incomplete histological study of them. There is unquestionably a large field for future discoveries in the microscopic study of tumors.

It is often convenient to divide tumors into those which are *malignant* and those which are *benign*. Clinically, the division may have a certain justification, but it can never be made exact, because any tumor may be malignant in consequence of its situation in the body, although ordinarily in consequence of its slow growth, its encapsulation, and its lack of metastases, it would be classed as benign.

Virchow divided the true tumors into the following three groups:

1. *Histoid tumors*, those into whose structure only one tissue of the body enters (fibroma, osteoma, etc.).
2. *Organoid tumors*, those into whose structure several tissues enter (adenoma, carcinoma, etc.).
3. *Teratoid tumors*, those into whose structure whole systems of the body enter.

These divisions were further systematically subdivided and the tumors classified according to the normal tissues which they resembled.

From another point of view tumors are sometimes divided into the two following classes:

1. *Homologous tumors*, those which resemble the tissue from which they arise.
2. *Heterologous tumors*, those which are unlike the tissue from which they arise.

Both histoid and organoid tumors may be homologous (a chondroma from the cartilage of a joint or an adenoma from the mammary gland) or heterologous (a round-cell sarcoma from the peritoneum or a carcinoma from the stomach). It is important to bear in mind that homologous and heterologous are not synonymous with benign and malignant.

Virchow's classification of tumors into three groups is practically followed by many pathologists at the present day, although the headings of the groups are usually changed into the following:

1. *Connective tissue tumors.*
2. *Epithelial tumors.*
3. *Mixed tumors.*

The objections to this classification are that the word epithelial is used partly to refer to the character of the cells, partly to refer to a tissue derived from the ectoderm, as when a glioma is said to be of epithelial origin.

As a matter of fact, some epithelial tumors may originate from any one of the three embryonic germ layers. In like manner the term connective-tissue tumors, as generally employed, refers to tumors derived from the mesoderm, when it should include only a part of those derived from the mesenchyma. Moreover, many writers include gliomata under the connective-tissue tumors.

A few writers attempt no classification of tumors, while others believe that they should be divided according to the organ or tissue from which they arise.

Unquestionably, the proper classification of tumors must be like that of normal tissues. It must be

1. *Embryological*, based on the origin of the various cells from the three primitive germ layers and the various structures to which they give rise, and

2. *Histological*, based on the differentiation of the cells and their intercellular substances.

For this reason a list is given of the three embryonic germ layers and of the tissues and organs derived from them.

The Three Embryonic Germ Layers.

A. Ectodermal.

1. *Epidermis*, including:
(*a*) Epidermal appendages.
(*b*) Lens of eye.
2. *Epithelium* of:
(*a*) Cornea.
(*b*) Olfactory chamber.
(*c*) Auditory organ.
(*d*) Mouth, including oral glands, enamel organ, hypophysis.
(*e*) Anus.
(*f*) Chorion, fœtal placenta.
(*g*) Amnion.
3. *Central Nervous System:*
(*a*) Brain, optic nerve, retina.
(*b*) Spinal cord.
(*c*) Ganglia.
(*d*) Peripheral nerves.
(*e*) Ependymal cells of ventricles and neural canal.
(*f*) Neuroglia cells.
4. *Sympathetic Nervous System*, including part of the adrenal glands.

B. Mesodermal.

1. *Mesothelium.*
(*a*) Epithelium of peritoneum, pericardium, pleura, urogenital organs (Wolffian body, kidney, ovary, oviduct, uterus, vagina, epididymis, testicle).
(*b*) Striated skeletal and cardiac muscle cells.
2. *Mesenchyma.* (The primitive type of mesenchymal cell is preserved with slight modifications in the lymph nodes, and in the mucous membranes of the intestine and uterus)
(*a*) Connective-tissue cells (with fibrillar, reticular, and elastic intercellular substances).
(*b*) Supporting tissues (cartilage and bone).
(*c*) Smooth muscle cells.
(*d*) Fat cells.
(*e*) The so-called endothelium of the blood-vessels and lymphatics, and of the arachnoid, synovial, bursal, and corneal spaces.
(*f*) Pigment cells
(*g*) The epithelium of the adrenal.
(*h*) Nerve sheaths.
3. *Mesamaboids.*
(*a*) Red blood corpuscles.
(*b*) Leucocytes.
(*c*) Myelocytes

C. Entodermal.

1. *Notochord.*
2. *Epithelium* of:
(*a*) Digestive tract, viz.: œsophagus, stomach, liver, pancreas, small intestine, yolk sac, large intestine, cæcum, vermix, rectum, bladder (from allantois).
(*b*) Pharynx, Eustachian tube, tonsils, thymus, parathyroids, thyroid.
(*c*) Respiratory tract (larynx, trachea, lungs).

From the embryological point of view the principal types of tumors can be classified as follows:

A. Tumors Derived from the Ectodermal Germ Layer.

1. Adenoma, including cysts and other tumors from epithelium of tooth papillæ.
2. Carcinoma.
3. Syncytioma from fœtal placenta.
4. Neuroma.
5. Glioma.
6. Epidermoids (cholesteatoma) and simple dermoids due to inclusions of epidermal cells.

B. Tumors Derived from the Mesodermal Germ Layer.

(*a*) *From the Mesothelium.*
1. Adenoma, adenocystoma.
2. Carcinoma.
3. Rhabdomyoma.
4. Teratoid tumors (ovary, testicle).
5. Congenital tumors of urogenital tract.
6. Tumors of testicle with embryonic type of cells.
(*b*) *From the Mesenchyma.*
1. Fibroma, fibrosarcoma, spindle-cell sarcoma.
2. Myxoma, myxosarcoma.
3. Chondroma, chondrosarcoma.
4. Osteoma, osteosarcoma.
5. Leiomyoma, malignant leiomyoma.
6. Lipoma.
7. Melanoma.
8. Hypernephroma.
9. Angioma, angioendothelioma.
(*c*) *From the Mesamaboids.*
1. Lymphosarcoma.
2. Chloroma.
3. Myeloma.
4. Leukæmia (lymphatic, myelogenous).

C. Tumors Derived from the Entodermal Germ Layer.

1. Chordoma (from notochord).
2. Adenoma.
3. Carcinoma.
4. Thyroid and parathyroid tumors.

From an examination of the above classification it is evident that certain tumors, such as adenomata and carcinomata, can arise from all three of the germ layers, while many other tumors, such as gliomata and myomata, can arise only from differentiated parts of single germ layers. It is possible that the epithelial growths derived from the different germ layers may eventually show some differences in structure or in chemical properties, but at present no marked differences are recognizable. Therefore, for the sake of convenience, it is customary to consider all epithelial tumors of a similar structure—as, for example, carcinomata—under a single heading, and to distinguish only those of which the cells or cell products are so characteristic that they can be readily recognized, as, for example, adenomata of the thyroid or carcinomata of the adrenal.

In taking up tumors in detail it is customary, as in dealing with normal tissues, to group together, largely for practical purposes, those that in the character and arrangement of the cells, and in the production or nonproduction of intercellular substances, are morphologically most closely related. Just as carcinomata are considered together without reference to the germ layer from which they arise, so other tumors are grouped together—as, for example, the gliomata—with certain new-growths of mesenchymal origin, because of the production of fibrillar intercellular substances.

One fault at present universally made is the grouping together of certain rapidly growing tumors and the separation of them from the slower-growing forms to which they are related. I refer particularly to the sarcomata.

A carcinoma is treated as an entity; it represents a certain type of tumor. The two extremes in its rapidity of growth are distinguished as scirrhous and medullary carcinomata: all intermediate stages occur.

A glioma is a definite tumor of which the extremes in rate of growth are represented by the dense fibrous and the soft cellular forms, while all intermediate forms occur.

The same method should be adopted in the discussion of tumors arising from smooth muscle cells (leiomyoma, malignant leiomyoma), from connective-tissue cells (fibroma, fibrosarcoma, spindle-cell sarcoma), from endothelium (hemangioma, hemangio-endothelioma), etc.

Unquestionably, the reasons for grouping the rapidly growing tumors of different origins together have been at least three: First, the common properties of rapid growth and of malignancy, due partly to infiltration of surrounding tissues and partly to giving rise to metastases; second, the difficulty of determining the origin of certain sarcomata owing to the lack of differentiation of the cells; and third, the fact that several of the tissues are very closely related (connective tissue, cartilage, bone) and are often present together in a single tumor. The two latter difficulties have not yet been entirely overcome, but it is believed that with better histological technique and more careful observation they may be.

It does not matter much in what order tumors are studied, but as a rule those most closely resembling simple normal tissues are taken up first because most easily understood by beginners.

It is not claimed that the following list of tumors is complete, but it includes the most characteristic types and permits of the insertion of others as their distinguishing characteristics become recognized and generally accepted.

I. Non-epithelial Tumors.

A. Tumors of which the Cells Secrete an Intercellular Substance.—(*a*) *Fibroma, Fibro-sarcoma, Spindle-cell Sarcoma.* These names are applied to tumors originating from connective-tissue cells, and represent the three rates in the rapidity of growth under which they are all grouped. These cells produce two kinds of fibrils which are chemically and morphologically different (see *Sarcoma* for staining methods). One variety is intercellular and corresponds to white fibrous tissue. The other variety of fibrils bear the same relation to the cell that neuroglia fibrils bear to neuroglia cells; they touch the surface of the protoplasm and continue indefinitely in two directions. They are numerous in the cellular forms of tumors and very scarce in the fibrous forms.

(*b*) *Myxoma, Myxosarcoma.* Myxomatous tissue consists of connective-tissue cells with branching protoplasmic processes: between the cells are numerous intercellular fibrils more or less separated from each other by a fluid containing an excess of mucin. The term myxoma is applied to a slow-growing tumor composed of myxomatous tissue, and the term myxosarcoma to a rapidly growing one.

(*c*) *Chondroma, Chondrosarcoma.* The first name is applied to the slow-growing, the other to the rapidly growing tumors which produce the homogeneous substance characteristic of cartilage. Connective-tissue fibrils may occur in any of these tumors, but elastic fibrils are found only in the more slowly growing ones.

(*d*) *Osteoma, Osteosarcoma.* Tumors of which the cells produce a homogeneous intercellular substance in which lime salts are deposited are classed according to their rapidity of growth as osteomata or osteosarcomata. An *osteoid sarcoma* is one in which the ground substance of bone is formed without the deposition of lime salts in it taking place. The *giant-cell sarcoma* probably represents, in the majority of cases at least, a further differentiation of the cells of this type of tumor in an attempt to form osteoclasts.

(*e*) *Lipoma.* This is a tumor composed of fat tissue. Two forms occur: in the common form each fat cell is enormously distended by a single drop of fat, the protoplasm is reduced to a thin envelope, the nucleus is flattened and pressed to the periphery of the cell. In the rarer form the fat occurs in numerous large and small droplets scattered fairly uniformly in the protoplasm, and the nucleus remains in the centre of the cell. This type of fat cell occurs to some extent in normal human fat tissue and is quite common in some of the lower animals. The fat cells in lipomata are held together by intercellular connective-tissue fibrils which possibly are produced by the fat cells.

(*f*) *Leiomyoma, Malignant Leiomyoma.* Smooth muscle cells have two sets of fibrils: the coarse or myoglia fibrils are situated at the periphery of the protoplasm, run from cell to cell, and can easily be stained differentially; the fine contractile fibrils are situated between the nucleus and the periphery of the cell. Between the muscle cells and surrounding them closely is a network of intercellular fibrils probably produced by the smooth muscle cells. In the ordinary leiomyoma, all three kinds of fibrils are produced. In the more rapidly growing malignant leiomyomata the intercellular fibrils are formed in great abundance and so far as my experience goes many or practically all of the smooth muscle cells are sufficiently differentiated to produce the coarse myoglia fibrils.

(*g*) *Glioma.* The neuroglia is the connecting and supporting tissue of the central nervous system and is of ectodermal origin. It is composed of cells and of fibrils. The fibrils are in intimate contact for a part of their course with the cell from which they arise and then continue away from the cell in two directions running between the other cells. The fibrils of neuroglia cells have characteristic chemical properties which permit of their being stained by certain differential methods. A glioma is a tumor composed of neuroglia tissue. All gradations occur between dense fibrous forms containing few cells and many fibrils, and soft cellular forms with few fibrils.

Chordoma. This is a tumor derived from remains of the notochord. It consists of large pale cells surrounded by a homogeneous intercellular substance and containing vacuoles in the protoplasm.

B. Tumors of which the Cells are Embedded in a Reticulum.—(*a*) *Malignant Lymphoma.* This term is applied to a series of tumors derived from the lymphocyte series. The cells vary from undifferentiated lymphocytes such as fill the germinative centres of Flemming to the typical differentiated lymphoid cell found in the circulation. The cells vary not only in histological differentiation but also in size. They lie in the meshes of a connective-tissue reticulum which is furnished by the tissue in which the tumor cells grow. Tumors of this series vary much in rate of growth.

(*b*) *Chloroma.* This tumor is closely related to the malignant lymphoma, but is distinguished by the fact that some or all of the nodules of new growth are, for some reason yet unknown, of a greenish color. The tumor arises from cells in the bone marrow.

(*c*) *Myeloma.* This is a tumor which likewise arises from cells of the bone marrow, and which is closely related to the malignant lymphoma. The cells are characterized by having basophilic protoplasm. They resemble plasma cells except that they possess distinct nucleoli.

(*d*) *Leukæmia.* It is not impossible that both forms of leukæmia are true tumors, of which the cells find the conditions in the blood favorable for growth and multiplication.

C. Non-Epithelial Tumors Having an Alveolar Structure.—(*a*) *Melanoma.* Chromatophores or pigment cells are certain differentiated cells of mesenchymal origin which occur normally in the choroid and iris of the eye, and in certain situations in the pia and in the skin. They are also present more or less abundantly in the congenital soft warts or nævi (abnormalities, not true tumors) of the skin. Tumors arising from these pigmented cells are called melanomata or melanotic sarcomata. The cells do not produce an intercellular substance, but like the cells of the carcinomata are arranged in alveoli more or less separated by a connective-tissue stroma containing blood-vessels.

(*b*) *Alveolar Sarcoma.* This group of tumors must be regarded with suspicion. Some included in it may have been slightly pigmented melanomata; others were unquestionably carcinomata. Possibly rapidly growing tumors, arising from striated muscle cells, possess an alveolar arrangement and may have been included under this heading.

D. Tumors Arising from Endothelial Cells.—(*a*) *Hæmangioma, Hæmangio-endothelioma.* The congenital vascular nævi of the skin and the cavernomata of the liver are abnormalities, not true tumors, but they may give rise to autonomous vascular tumors. A hæmangioma is a slow-growing tumor composed of blood-vessels, which exhibits the characteristics of true tumors. The vessels often dilate and become cavernous in type. Rarely the tumors are multiple. The term hæmangio-endothelioma is applied to rapidly growing tumors arising from the endothelium of blood-vessels. As the lumina of the new-formed capillaries often become occluded by intravascular proliferation or by rupture of continuity, rows of anastomosing cells and concentric cell masses are usually formed in parts, at least, of the tumors. There is a gradual growth of connective tissue between the cells separating them from each other.

(*b*) *Lymphangioma, Lymphangio-endothelioma.* These names are applied to the slowly and rapidly growing tumors arising from the endothelium of lymph vessels.

(*c*) *Dural Endothelioma.* Tumors distinguished by this title arise from the endothelium lining the arachnoid space. They vary in rate of growth from slow to rapid. The structure of the tumors varies greatly; it may be cellular like a sarcoma or more or less fibrous like a cellular fibroma. The cells may have an alveolar arrangement with the cells often grouped in whorls, or the cells may be more or less uniformly distributed in the stroma.

E. Tumors Arising from Nerve Cells.—(*a*) *Neuroma.* This term is often applied to a tumor-like mass which follows amputation of a limb, and is due to an attempt at regeneration made by the axis cylinders of a cut nerve. As an axis cylinder is only a process of a cell it cannot give rise to a true tumor. A true neuroma is a tumor composed, in large part at least, of ganglion cells which may produce medullated or non-medullated nerve fibres. Neuromata are rare, and arise chiefly from the sympathetic nervous system.

2. Epithelial Tumors.

In this group of tumors epithelial cells play as a rule the more important part. Like the cells in the tumors already described they cannot exist by themselves, but are always accompanied by a certain amount of connective tissue and blood-vessels on which they depend for support and nutrition. In some of the tumors the stroma is slight in amount; in others it is abundant, rapidly growing, and suggests active inflammatory tissue; in still others the connective tissue accompanying the epithelium is very abundant, and cannot be regarded as stroma but as part of the tumor formation.

A. From surfaces covered with epithelium tumors arise which are divided into two groups, according as they are elevated above the lining epithelium or invade the tissues below it.

(*a*) *Papillary fibroma*, a tumor composed of papillary outgrowths of connective tissue and blood-vessels, covered externally with a single layer of epithelium, or with a pavement epithelium. Sometimes the connective tissue is very slight in amount, sometimes very abundant.

(*b*) *Carcinoma*, a tumor composed of branching and anastomosing columns and masses of epithelial cells which invade the tissue beneath the lining epithelium, from which the tumor arises and which give rise to metastases.

B. From the epithelium lining glands, two general types of tumors arise.

(*a*) *Adenoma*, a tumor composed of new-formed glands which do not invade the surrounding tissue. Closely related to the adenoma are on the one hand the *adenocystoma*, an adenoma in which some of the glands dilate to form cysts, and the *papillary adenocystoma*, an adenocystoma with papillary projections from the wall. This latter tumor sometimes approaches the carcinoma in malignancy, and is even classed by Ribbert as one form of it. On the other hand, the connective tissue surrounding the glands may play an equal or even more important part than the epithelium, and then we get the *adenofibroma*, or, if papillary ingrowths occur, the *intracanalicular papillary adenofibroma*.

(*b*) *Malignant adenoma, adenocarcinoma, carcinoma.* A closely related group of tumors, morphologically somewhat different, biologically alike, which are often included under the term carcinoma. They also correspond biologically with the carcinoma of the first group of epithelial tumors.

The term carcinoma is unfortunately employed in two ways—biologically as a designation for all malignant epithelial tumors, and morphologically to distinguish in malignant epithelial new growths the epithelium growing in solid masses from that which grows in the form of glands or cysts.

There is a certain tendency to give a special name to all epithelial tumors coming from a certain organ, such as malignant hypernephroma for epithelial tumors of adrenal origin, provided the cells or their secretions are very characteristic.

In the above classification those tumors in which epithelium and connective tissue play an essentially equal part are often separately considered under the heading fibro-epithelial tumors. This would include papillary fibromata of the skin and the adenofibromata of the breast.

It is to be noted, however, that adenomata of any organ imitate that organ not only in regard to the glands, but also in regard to the amount and character of connective tissue which is between the glands. In the liver and adrenal there is very little connective tissue and adenomata of these organs exhibit the same condition. But in the mammary gland, where there is always a great amount of dense connective tissue between the glands, the adenomata arising there have much connective tissue associated with them. It would seem as if the two tissues worked together in an attempt to form mammary-gland tissue.

C. Cysts Lined with Pavement Epithelium.—Cysts lined with a single layer of epithelium belong in one of two classes. The first are due to dilatation of pre-existing glands or cavities under the influence of retained secretions. The second are true tumor formations and begin as adenomata, of which some of the glands dilate and fuse to form cysts.

There is another class of cysts which are lined with epidermis. Those due to the dilatation of the ducts of sebaceous glands (wen, atheroma) are certainly not tumors. There is another group, however, which is usually included among the new growths. These are the simple dermoids occurring chiefly along the lines of closure of the embryonic fissures and the cholesteatomata which are found almost exclusively in connection with the central nervous system. They are probably both to be regarded not as true tumors, but as embryonic inclusions and displacements. The dermoid cysts enlarge as sebaceous cysts do under the influence of retained secretions. If the secretions could escape they would not enlarge any more than do the fistulæ originating from branchial clefts.

The cholesteatoma is due to the inclusion within the central nervous system of ectodermal cells, which would normally form epidermis. The apparent tumor is due to the gradual accumulation of dead desquamated epidermal cells.

The simple dermoids and the cholesteatoma belong in the same class with aberrant adrenal rests. They are unquestionably under the physiological control of the body. They can give rise to tumors, but are not themselves true tumors. They have been classed with the tumors largely because under the influence of retained secretions they often attain a considerable size.

3. Mixed Tumors.

There are three principal groups of mixed tumors which require attention. It is possible, however, that the fibro-epithelial tumors should be added to them as the simplest type of mixed tumors.

A. *Mixed Tumors of the Salivary Glands.*—They develop most commonly in or near the parotid. They are nodular tumors of varying size which are usually benign, but may become malignant. They are composed of tissue elements derived in part from the ectoderm, in part from the mesoderm. The latter germ layer may give rise not only to connective tissue, but often to cartilage and more rarely to bone, fat, and lymphoid tissues, and even to striated muscle cells. The epithelium of ectodermal origin may occur in the form of glands or in solid masses as in a carcinoma.

These tumors probably arise from embryonic displacements of cells of the ectoderm and mesoderm during the formation of the branchial arches and of the parotid and submaxillary glands.

B. *Mixed Tumors of the Genito-Urinary Tract.*—They occur most commonly in the kidney, but arise sometimes in the uterus and vagina, and even in the wall of the bladder. They are congenital tumors which are always malignant, and may give rise to metastases. They are composed of rapidly growing connective tissue which resembles sarcomatous tissue, of embryonic striated muscle cells, of tubular structures lined with epithelium, and occasionally of fat tissue and cartilage. These tumors unquestionably arise from the displacement, at an early stage of embryonic development, of undifferentiated cells, which under normal conditions are capable of giving rise to differentiated cells such as occur in the tumors.

C. *Teratoma.*—This group of tumors can be divided into two subdivisions.

(*a*) *Embryoma.* In the ovary and to a less extent in the testicle tumors occur which vary from a simple to a very complex structure. They may contain practically all the different tissues present in the body, *i.e.*, all three embryonic germ layers are represented. It is probable that these tumors arise from undifferentiated cells which under normal conditions are capable of giving rise to embryos, *i.e.*, from ova or more probably from cells which give rise to ova.

(*b*) *Fœtus in Fœtu.* Very complicated tumors, more or less similar in structure to those occurring in the ovary and testicle, sometimes occur in other parts of the body. They are probably due to the inclusion in a fœtus of an ovum or of cells developed from an ovum, which under normal conditions would give rise to another fœtus.

Origin of Tumors.—A certain number of tumors unquestionably arise from cells which during embryonic development are displaced from the site where they belong. Some of these cells are displaced at an early stage of cell differentiation, and hence are capable of producing tumors of a complex nature, containing a variety of tissues, as for example the mixed tumors of the kidney. Other cells are displaced at a later period of development when they are more or less completely differentiated, and in consequence they give rise to tumors consisting essentially of a single kind of cell, as for example the tumors of adrenal origin.

Of these displacements of embryonic cells the commonest and most easily recognized are the aberrant adrenals or hypernephromata. Their size probably corresponds to the amount of gland tissue which they would have produced if they had remained in their proper situation. Small, misplaced spleens are not at all uncommon. Displaced bits of pancreatic tissue are less frequent. The so-called cholesteatomata found in connection with the central nervous system, the remains of branchial clefts and of the lower end of the neural canal, and the gland like structures so common in the wall of the oviduct are all examples of cells or groups of cells displaced during embryonic development. Pigmented and vascular nævi are still other examples which should, however, probably be classed as abnormalities rather than as displacements. Some of these "fœtal rests" become so large in consequence of the accumulation of retained secretions (the cholesteatoma and the simple dermoid) that they are usually classed as tumors.

It is probable that all of these displaced tissues are under the normal physiological control of the body. They can give rise to tumors, but are not themselves new growths.

Certain displacements of embryonic tissue are recognized only by the tumors to which they give rise, as for example those from which come the mixed tumors of the genito-urinary tract and of the salivary glands.

The adenofibromata of the breast may be derived from displacements in post-embryonic life, at the time when the mammary gland is developing. They certainly suggest an attempt at the formation of mammary-gland tissue.

The important point to bear in mind in regard to these tumors which unquestionably arise from embryonic displacements of tissue, such as the malignant hypernephromata, and the mixed tumors of the urogenital tract, is this, that they are as malignant as any tumors which exist, and that they give rise to metastases.

Etiology of Tumors.—In regard to the cause of tumors we know absolutely nothing. Bacteria, protozoa, and blastomycetes have been claimed to be the active agents in the production of some of them, particularly of carcinoma. It must be acknowledged that blastomycetes produce a curious form of tissue proliferation containing great numbers of endothelial cells, which to an unskilled observer might suggest an epithelial growth, but the result is granulation tissue, not a true tumor. It has been claimed that trauma (acute injury and chronic irritation) may so stimulate the cells of a part that a tumor formation is the result, but it is impossible to regard this as a general cause, although in certain cases it is possible that it is the exciting cause.

We thus come back to displaced cells as a possible solution of the question. In many cases, certainly, tumors arise from them, but the reason for it we are unable to understand, because most of these tissue displacements persist throughout life without leading to anything abnormal. Possibly a series of experiments with displaced tissues of various sorts might throw some light on the subject. Certainly at present such experimentation is the most promising field for investigation.

F. B. Mallory.

TUNNELLING, DANGERS OF.—The scope of this article is to deal with such explosives as are generally used in public or private works of improvement, the effects of the explosion upon the workingmen employed, and the way in which accidents with such explosives frequently occur.

I. Explosives Used in Blasting.—There are numerous kinds of explosives: Gunpowder, guncotton, nitroglycerin, dynamites, picrates, fulminates, etc. It is not the purpose of this article to deal with all of the different kinds of explosives, but simply with those which come into common use.

The principal ingredients of the various explosives are potassium nitrate, sodium nitrate, ammonium nitrate, potassium chlorate, nitric acid, sulphuric acid, sulphur, the hydrocarbons, benzene, toluene, naphthalin, carbohydrates, cellulose, alcohols, glycerin, ethers, acetone, camphor, vaseline, paraffin, kieselguhr, randanite, tripoli, coal dust, and the alkaline carbonates.

Gunpowder is of two kinds—nitrate and chlorate. Ordinary black gunpowder belongs to the *nitrate* class, and is composed of potassium nitrate, 75 parts; charcoal, 15 parts; sulphur, 10 parts. There are many special powders of this class which vary, not so much in their composition as in their shape, size of the grain, density, and hardness, such as hexagonal, perforated, prismatic, etc. Other powders vary only as to the nitrate used, whether barium nitrate, strontium nitrate, or sodium nitrate.

The results of the explosion of these powders vary. The greater part of the product is represented by sulphate of potash, carbonic acid, and nitrogen, but there is also to be found potassium carbonate, sulphide, hyposulphate, and sulphocyanate, ammonium carbonate, carbon monoxide, carbon dioxide, hydrogen, hydrogen sulphide, and marsh gas.

There are quite a number of *chlorate* mixtures or powders, most of which—as Harvey's, Davey's, Hill's, etc.,—are used for fuse composition; but, as they are attended with great danger in handling, they are of no great practical value.

The picrates are made with a basis of picric acid, or trinitro-phenol. These powders are used almost exclusively in France.

Borlinetto's powder is composed of potassium picrate and potassium nitrate with charcoal.

Brugère's powder is composed of ammonium picrate with potassium nitrate.

Melinite is composed of a mixture of fused picric acid and trinitrocellulose dissolved in a mixture of ether and alcohol; in other words, guncotton dissolved in ether, to which is added picric acid.

Lyddite, the English explosive, is identical with melinite. If fully exploded, these powders deflagrate into nitrogen, carbonic oxide, or carbonic acid, hydrogen, carbonate of potash, etc.; therefore the gases produced by them are not very injurious in character.

Other explosives of the nitro-substitution class are mono-, di-, and trinitro-benzene. *Bellite* and *Securite* (both composed of ammonium nitrate with meta-dinitrobenzene) are very powerful and yet safe to handle. Finally, there are nitrotoluene, mono-, di-, tri-, and tetranitronaphthalin, *Volney's powders* (mixtures of nitrated naphthalin, saltpetre, and sulphur), *Favier powders*, *Emmensite* (similar to picric acid), *Gelbite*, and *Roburite*.

Roburite is composed of ammonium nitrate with chlorinated dinitrobenzol, and is a yellow-brown powder with an odor of bitter almonds. It cannot be exploded by concussion, pressure, friction, shock, or fire, but only by a powerful detonator, such as 1 gm. of the fulminate of mercury.

Nitroglycerin is the most powerful of all explosives. But on account of the danger in handling it, it is not used as much in blasting operations to-day as formerly, but is the base of other high explosives. It is composed of nitric acid, sulphuric acid, and glycerin. It is an odorless, colorless (or slightly yellow) liquid, with a sweetish taste, insoluble in water, but soluble in ether or wood alcohol (methyl alcohol). Mixed with wood alcohol it loses its explosive property, but by adding water to the mixture it separates and can again be used as an explosive. It evaporates at 212° F., and freezes at about 30° F. Some of its incompatibles are muriate of ammonia, sulphate of iron, and the sulphides generally. It is decomposed by sulphuretted hydrogen and sulphur is precipitated; it is also decomposed by calcium sulphide. I mention these as they can be used as antidotes for poisoning by nitroglycerin.

Nitroglycerin explodes from pressure, or from a blow, or at 306° F. Properly to explode nitroglycerin great heat and pressure are needed. If it is exploded by means of gunpowder the explosion is not general and a part is not exploded. The method now in vogue is to use fulminating caps, and if these are of sufficient size and properly made they effect a complete detonation.

A cause insufficient to explode nitroglycerin in wood or paper will explode it in tin or other metals. Confinement or compression makes nitroglycerin and its compound explode more easily.

The result of the explosion of nitroglycerin gives water, 20 parts; carbonic acid, 58 parts; oxygen, 3.5 parts; nitrogen, 18.5 parts. And according to Nobel, 1 litre of "blasting oil" gives 10,400 litres of gases.

In point of rapidity the explosion of nitroglycerin is practically instantaneous. The characters of the products of explosion of many of the compounds are alike, but in the case of some they vary according to circumstances and condition, such as the method adopted for producing a high temperature, pressure, expansion, etc.

By mixing nitroglycerin with some porous substance it is readily absorbed, and produces an explosive comparatively safe to handle. These mixtures of nitro-compound are what is commonly known as *dynamite*.

The names of the various dynamites are Giant powder No. 1 and No. 2; Dualin, Atlas A and B, Vulcan, Judson, Rendrock, Hercules, American Safety, Carbonite, Stonite, Horsley, Dynamite de Trauzl, and Gelignite.

For the purposes of study there are practically two classes of dynamite, which might be termed inorganic and organic, according to the absorbent used. As a type of one class is that made with infusorial earth, kieselguhr, a soil found in Germany and which is composed of siliceous diatoms; and of the other, that made with ground wood pulp or sawdust. Others still are made from a combination of both kinds. The results of the explosion, however, are practically the same in either case, except that the dynamite made with an organic absorbent yields an additional amount of carbon.

As a type of the first class we have Giant powder No. 1: nitroglycerin, 75 parts; kieselguhr, 24.5 parts; sodium carbonate, 0.5 part. And as a type of the second class, we have the American safety powder: Nitroglycerin, 68.81 parts; sodium nitrate, 18.35 parts; wood pulp, 12.84 parts.

Dynamite is safe or unsafe to handle, according to the amount of oil (nitroglycerin) that is absorbed. The capacity of the absorbent varies with the temperature. Thus, a powder that is comparatively safe at 50° F. may be leaky at 100° F.

When dynamite is frozen it is more difficult to explode, and one cap will rarely make it deflagrate.

Guncotton is made by putting ordinary cotton in nitric and sulphuric acids. The cotton is first steamed with caustic potash, and then immersed in a mixture of sulphuric and nitric acids in the proportion of three to one by weight; and then it is washed until free from every trace of acid, and dried in a cool chamber.

Guncotton is harsher to the touch than ordinary cotton and is insoluble in water. It is soluble in ether, ammonia, and acetone. If a flame is applied to it, it burns with a flash, but without explosion. It is one of the safest of explosives. When properly exploded *in vacuo* the resultant gases are carbonic oxide, carbonic acid, marsh gas, olefiant gas, nitric oxide, nitrogen, hydrogen, aqueous vapor. Guncotton in itself is not used for blasting, but is sometimes mixed with other ingredients.

Tonite is composed of guncotton 52½ parts, barium nitrate 47½ parts.

Potentite is composed of guncotton 66.20, potassium nitrate 33.80.

Explosive gelatin is made by dissolving guncotton in nitroglycerin by the aid of heat, the result being a jelly-like mass. It is of a dark-yellow color. Unconfined it will burn without exploding. If confined and heated to 399° F., it explodes violently. It is more sensitive when frozen than in the unfrozen state, and can be readily detonated by the impact of a bullet. In this it differs from dynamite, which is less apt to do so.

Forcite is a gelatin dynamite largely used in the United States, and is gradually supplanting all other forms of dynamite. As this is the dynamite now most commonly used, I give its full composition:

Nitroglycerin	98 parts	Gelatin	50 parts.
Nitrocotton	2 parts		
Sodium nitrate	76 parts	Dope	50 parts.
Sulphur	3 parts		
Wood tar	20 parts		
Wood pulp	1 part		

The smokeless powders are composed principally of insoluble and soluble nitrocellulose.

Cordite, the explosive adopted by Great Britain, is composed of nitroglycerin, guncotton, and mineral jelly (vaseline). The gases evolved by explosion are carbonic acid, carbonic oxide, nitrogen, and hydrogen. Other powders of this class are Ballistite, Maximite, Schultze powder, Wetteren Indurite, Ritleite, Leonard, etc.

Other explosives belonging to no especial class are *Rack-a-rock*, composed of potassium nitrate and mononitrobenzene.

Hellhoffite, composed of metadinitrobenzene and nitric acid.

Oxonite, composed of picric acid and nitric acid.

Panclastite, composed of nitrogen tetroxide and carbon disulphide.

Romite, composed of ammonium nitrate, nitronaphthalin, paraffin oil, and potassium chlorate. It explodes spontaneously.

Fulminate of mercury is used for exploders, percussion caps, and detonators. It explodes violently when compressed or struck or rubbed between hard surfaces, or when touched with concentrated sulphuric acid or any ignited body. When used in a percussion cap it is, as a rule, mixed with potassium chlorate in the proportion of 75 parts of the fulminate to 25 of potassium chlorate.

There are many fulminates, but the fulminate of mercury is the only one in general use, except for toy caps, which contain fulminate of silver.

When it is exploded the following reaction may occur:
$5\,HgC_2N_2O_2 + 4KNO_3 = 5Hg + 8\,CO_2 + 7N_2 + 2\,K_2CO_3$.

II. Dangers Encountered.—Asphyxia, or partial asphyxia, with a general poisoning and consequent disturbance of the system, is frequently met with in the construction of tunnels in the present day, and is due to the use of these "high explosives"; for in the removal of rock, in construction work of this nature, dynamite or nitroglycerin is used in considerable quantities.

When the blasting is done in open-cut work, as on railroads, the gases, after the explosion, immediately distribute themselves in the atmospheric air, and no effect has been noticed on the workmen employed. But when the explosions take place in tunnels, or in mining or other partially closed cavities, and the gases or residue are slow to escape from the mouths of the tunnel or up an air-shaft, serious deleterious effects are produced.

There are two classes of cases of poisoning produced by breathing the products of the explosion of such materials: First, acute cases, in which a considerable quantity of the residue is inhaled at one time; and secondly, chronic cases, or those in which a small amount is constantly breathed for a long time. The acute cases vary according to the amount inhaled.

Where the amount of dynamite used is not large, or where after the explosion a considerable quantity of fresh air has been mixed with the products of the combustion, or where the workman has, after a few breaths, become giddy and is pulled away by others and sent to the surface, the effects produced are the following: a trembling sensation, flushing of the face, succeeded sometimes by pallor, frequently nausea, sometimes vomiting, with throbbing through the temples, and fulness in the head, as if it would burst, followed by an intense headache characteristic of poisoning by nitrites—similar to that of nitrite of amyl, only not so violent, but more persistent, frequently lasting forty-eight hours. The heart's action is increased, and the pulse is full and bounding, though somewhat compressible, and varying in rate from 100 to 140. The condition is described by the workman as a "dizziness." He feels as if drunk, or as if his head is swelled.

In the second class of acute cases, in which a man goes into the tunnel immediately after the explosion, and is brought in contact with a large percentage of the poisonous materials, the effects are giddiness, immediately followed by unconsciousness, and the patient presents the usual appearance of asphyxia.

Sometimes in these cases the pulse is full and bounding, though very compressible, but in most of the cases it is alarmingly weak. Generally there is a great pallor, though this may be partially due to working underground. The comatose condition soon passes away, and is succeeded by drowsiness, languor, cold perspiration, intermittent pulse, and generally nausea and vomiting. Sometimes the breathing is spasmodic, and frequently there are hiccough, and after a time a severe headache.

Nearly all of these cases, however, no matter how serious they seem at the time, end in recovery. In the few cases in which death does occur, it is usually several hours after the patient has been removed from the tunnel, and is due to paralysis of respiration.

In the chronic cases, in which only a small amount of the gaseous products of the explosions is breathed daily, there are four prominent symptoms. These are headache, cough, indigestion, and disturbances of the nervous system. The headache is usually a continuing one, and varies in degree from a mere sense of fulness to a throbbing pain. The cough is similar in character to the cough of pertussis, or of malaria, and as cases of malaria are frequent among men engaged upon such works, one may easily mistake the cause.

Next in prominence to these symptoms come disturbances of the nervous system, as trembling, irritability, neuralgia. In fact, nearly, if not all, of the symptoms are attributable to this cause. Even the cough is in all probability due to the poisonous effect produced on the pneumogastric nerve.

With this nervousness is also associated indigestion, probably due to the same cause. Of course, with this latter symptom, the character of the food and the manner in which it was eaten must be taken into consideration; but as soon as a man with these chronic symptoms is taken from the tunnel and placed at work on top he steadily improves, and finally entirely recovers.

It is also noticeable that those who have previously suffered from dyspepsia, or from tic douloureux, or sciatica, or other form of neuralgia, are made worse by the dynamite smoke.

What are these symptoms due to?

The formula for nitroglycerin is $C_3H_5N_3O_9$. And the products from the combustion of this are written:
$4\,(C_3H_5N_3O_9) = 10\,(H_2O) + 12\,(CO) + 6\,(N_2O_2) + O_2$.

In other words, the products are water, carbonic oxide, and nitrogen dioxide, none of which would produce the symptoms above described with the exception of asphyxia.

A comparison of the above symptoms in the acute cases, with the phenomena produced by various-sized doses of nitroglycerin, shows them to be identical. This similarity between the symptoms from inhalation of the products of the explosion of dynamite, and those produced by the nitroglycerin itself, is so well marked that even miners themselves have noticed it. Frequently, when dynamite is frozen, a miner will place a cartridge in his boot to thaw it out, and the absorption of nitroglycerin through the skin will produce precisely the same symptoms as in the mild acute cases of the inhalation of the products before described.

Again, as another instance, I may cite the case of a miner who used his knife to cut a cartridge and afterward ate an apple cut with the same knife. In this case, according to his statement, the symptoms were similar to being "knocked out by powder smoke," only more severe; the headache persisting three weeks. On another occasion this same miner cut up some tobacco to smoke with a knife that he had used for dynamite, and he was again similarly affected. Here the heat from the tobacco smoke volatilized the fine particles of nitroglycerin on the tobacco below, and poisoning was produced by absorption through the lung tissue. No other conclusion can well be reached than this: that there are mixed with the gases produced unexploded particles of nitroglycerin in a volatile state; and these particles inhaled by the miners produce the effect described.

This fact can be conclusively proved by waving in the fumes, immediately after an explosion, a cold sheet of glass, and thus collecting upon it by condensation a small percentage of the nitroglycerin itself.

There is no doubt that the explosion of a large quantity of dynamite would produce sufficient gases of CO and N_2O_2 to produce asphyxia. Here we get the cyanosis and other symptoms of simple asphyxia, and we may get nausea and vomiting; but not the same disturbance of the sympathetic system, nor the continued chronic spasm of the vagus, nor the persistent headache pathognomonic of nitroglycerin poisoning.

Treatment.—In the way of prophylactic treatment the use of such apparatus or machinery, whether by blowing or by sucking, that will rapidly clear the tunnel or cavity from noxious gases or fumes, is to be recommended. When steam drills that are worked with an air compressor are used, they contribute largely to this end. It has also been found that the use of a large cap will explode a greater percentage of nitroglycerin than a small one, and this, to a certain extent, obviates the trouble. In certain cases, however, a cartridge—for some reason or other—does not explode, but burns like a candle, with considerable spluttering. In such an instance the amount of nitroglycerin volatilized is much greater than if an explosion had taken place, and consequently the effects are more deleterious.

For immediate treatment, such measures as are generally used in cases of asphyxia are of service. In addition, the use of cold to the head or the subcutaneous administration of atropine, ergotin, or other vaso-motor stimulant, is of necessity indicated and very efficacious. There is little doubt that the effects of nitroglycerin are produced by its decomposition and the formation of a nitrite in the body. "Treatment with ammonia restores normal color and normal functional power to nitrite-poisoned blood." So the carbonate and aromatic spirits of ammonia should be used internally, and it is also well for those in charge of such works to recommend to the workmen employed to carry with them small vials of this remedy for use in such cases.

The effects of nitroglycerin are also antagonized by sulphur. I have therefore given to many of the workmen sulphide of calcium, and these seemed to do better than those to whom it was not administered. This result, however, may have been partly due to the beneficial effects of the sulphide of calcium *per se*.

III. Manner in which Accidents Occur.—The methods by which accidents occur, and their effect upon the workmen employed, can be best understood if I narrate a few actual occurrences. Thus, the fulminate of mercury will explode violently when compressed. As an illustration of such explosion one of the workmen under my care endeavored to bend a cap so that he might more easily attach it to a dynamite cartridge; and, being ignorant of the conditions under which it would explode, he tried to bend it between his teeth. The result was that he lost half of his teeth, his cheek, and a portion of his ear.

Exploders or caps will also explode when struck a slight blow. Sometimes they are not properly attached to the dynamite cartridge or to the wire connected with the electric battery, and therefore the charge is not exploded. Under these circumstances the cartridge must be removed from the hole and a new cartridge and exploder put in its place. The removal of this cartridge with the exploder in it is attended with great danger. It is done with a long rod, sharp on the point, and with a little cup near the end. Thus with the point the cartridge is broken up, and with the cup it is drawn out of the hole. Should, however, the point of the rod happen to strike the fulminative mercury cap, it is almost sure to explode.

Numerous accidents of this kind occur. One particularly more gross in carelessness or ignorance than the others I will relate.

In firing, in the heading of a tunnel, it frequently becomes necessary to break up the large rocks that are brought down with a blast, so that they can be handled by the workmen. To do this, a single hole is drilled in the centre of the rock and a cartridge placed therein. This is fired when the heading is fired; but sometimes the cartridge becomes loosened and does not go off. On one such occasion a Norwegian seeing one of these holes in a rock that had not been broken up, he placed a bar in the hole and told his companion to hit it to see if there was a cartridge inside. He happened to strike the exploder, and both men were instantly killed, while a third lost his eyesight.

Compression in other ways may explode both the cap and the nitroglycerin; thus, on one occasion when a charge failed to explode, the foreman took a hose attached to the air compressor, and turning it into the hole endeavored to blow it out; the result was that it immediately exploded, his companion was instantly killed, and he himself died later from the injuries received.

Dynamite will not easily explode when frozen, but it can be made to explode even then under some circumstances. As an illustration, the powder man at one of the shafts on the Croton Aqueduct left half a cartridge in a pail of warm water in which he had been thawing it one evening. On the following morning, as it had been a cold night, the water in the pail was frozen with the cartridge at the bottom. Wishing to get the cartridge out of the ice in the pail, he placed it over the blacksmith's fire and blew upon it with the bellows. Both he and the blacksmith were thrown from the building, and from the powder man I removed more than eighty pieces of zinc from the pail.

Under proper conditions in the open air a dynamite cartridge will burn like a candle; but if heated rapidly beyond 306° F. it will explode. Thus, in the Park Avenue tunnel a number of papers, the packing from the boxes, and other inflammable articles were around the powder house. By some means these caught fire and a hot flame was instantly developed about the dynamite, the result being that the whole deflagrated.

A similar accident occurred at Spuyten Duyvil, where some powder, intended for use in making a new road, was stored in a small house. Some children playing in the neighborhood set fire to the grass near the powder house, and the result was an explosion.

In some parts of the country, as in certain mines in the West, where it is not desired to use a large amount of dynamite at any one time, instead of firing with electricity it is customary to use a powder fuse. Where the climate is warm the fuse is often kept with the dynamite, and then it sometimes happens that the nitroglycerin will exude from the cartridges and as a result the fuse which is kept with it will become soaked. Such a fuse will explode instantly, and sometimes even when kept separate from the cartridges they will get covered with machine oil and will then burn more rapidly than is intended. In an accident of this character in Arizona the explosion followed so rapidly the lighting of the fuse that one man could not get away at all, and his assistant had just time to turn his back, from which I later extracted many small pieces of stone.

In the case of nitroglycerin perhaps more accidents occur with the empty can than in any other way. Thus the foreman in a tunnel, who had just filled some holes with nitroglycerin and had emptied the can, set it down in such a manner that the tin in the bottom of the can bent with a slight snap. An explosion immediately followed, and it then became evident that sufficient nitroglycerin had remained in the can, adherent to the sides and the bottom, to drive the major part of the metal into his thigh and hip.

Illustrations of such accidents might be recorded indefinitely, but from many such the following rules have been formulated:

Always remember that the function of an explosive is to explode.

That accidents as a rule are due to carelessness and ignorance.

Workmen who handle nitroglycerin and dynamite should be provided with rubber gloves, to prevent absorption.

Powder for transportation should not be enclosed in a tight or metallic case.

Explosives should be stored at a sufficient distance from works not to be affected by concussion or by flying débris.

Tools and fuse or caps should be stored or transported separately.

The floor of the powder house should be covered with sawdust and sulphur to absorb and decompose any nitroglycerin that has leaked from a cartridge.

Smoking should not be allowed.

Explosives and powder house should always be marked "dangerous."

Caps must always be examined before attaching them to a cartridge.

In firing by electricity be sure that the wire is disconnected from the battery before attaching the cap or fuse.

Never attempt to remove a charge that will not explode.

Wooden ram rods should be used for charging holes.

Other rules can be formulated from the above article.

Thomas Darlington.

TURMERIC. See *Curcuma.*

TURNIP, WILD or **INDIAN.**—*Arum, Jack-in-the-Pulpit.* The corm of *Arisæma triphyllum* Torr. (American arum) and of *Arum maculatum* L. (European arum). Both these species are very common vernal plants in their respective countries, growing in swamps, along streams, and in other damp and shady places. The American corm is depressed, globose, very much wrinkled, and has a dense circle of curly roots, which arise from the top, around the stem, and descend about the corm. The European is oblong or ovoid, and has the roots at the base. Both usually are found in the market cut into transverse slices, which are white and very starchy. Both are pervaded by an intensely acrid and stinging juice when fresh, but which gradually disappears with drying and keeping, and is dissipated by heat. Small doses of the drug, before this change occurs, act as a very powerful abdominal stimulant, but afterward it is nearly inert. The dose is 0.5–1 gm. (gr. viij.–xv.). It should be given well diluted with mucilage or honey, to mitigate its sharpness. Its use has almost ceased.

Henry H. Rusby.

TURPENTINE.—*American Turpentine* (*Terebinthina*, U. S., P. G.; *Thus Americanum*, Br., *Galipot*, Cod. Med.). A concrete oleoresin obtained from *Pinus palustris* Miller, and from other species of *Pinus* (fam. *Pinaceæ* or *Coniferæ*). The species of pine here referred to form large forests in the Altantic and gulf belts of the Southeastern United States, where the turpentine is collected on an enormous scale. By the carelessness of the Government in permitting the present ruinous methods of collection, the destruction of the sources of this article is a question of a very short time only.

Deep gashes are cut in the trunks of the trees, near the ground, and hollowed out at the bottom so as to hold a pint or more of liquid, and, above these, slight cuts are made in the bark, from which the turpentine flows, and, running down, is collected in the "boxes," as the excavated gashes are called; from these it is ladled out from time to time as the boxes fill, and fresh hacks are occasionally made in the bark above to keep up the flow. The freshly collected turpentine is then filled into barrels and carried to the still, where the oil is distilled off, being the spirit of turpentine, as it is commonly called, of commerce.

Turpentine is described as occurring in yellowish, opaque, tough masses, brittle in the cold, crumbly-crystalline in the interior, of a terebinthinate odor and taste. The alcoholic solution has an acid reaction.

As indicated in its definition, turpentine consists of oil of turpentine and resin. A small amount of bitter substance is also present. Its properties, medicinally, are wholly those of the oil, considered below, which is present to the extent of from fifteen to thirty per cent., weakened by the resin, also considered below. The uses of all three of the articles, as well as their preparations, are considered together at the close of this article:

Oil of Turpentine (*Oleum Terebinthinæ*, U. S.; Br., *Spirit of Turpentine*) is defined as a volatile oil distilled from turpentine, and is thus described:

A thin, colorless liquid, having a characteristic odor and taste, both of which become stronger and less pleasant by age and exposure to the air.

Specific gravity: 0.855 to 0.870 at 15° C. (59° F.).

It boils at 155° to 170° C. (311° to 338° F.).

Soluble in three times its volume of alcohol, the solution being neutral or slightly acid to litmus paper; also soluble in an equal volume of glacial acetic acid.

Bromine or powdered iodine acts violently upon it.

When brought in contact with a mixture of nitric and sulphuric acids, it takes fire.

If a little of the oil be evaporated in a small capsule on a water bath, it should leave no more than a very slight residue (absence of *petroleum, paraffin oils,* or *resin*).

There is a rectified form of it (*Oleum Terebinthinæ Rectificatum*, U. S., P. G.) made by shaking up the crude oil with six times its amount of lime water and redistilling, which is thus described:

A thin, colorless liquid, having the general properties mentioned under oil of turpentine (see *Oleum Terebinthinæ*, above).

Specific gravity: 0.855 to 0.865 at 15° C. (59° F.).

Boiling point: about 160° C. (320° F.).

Its alcoholic solution should be neutral to litmus paper.

If about 10 c.c. of the oil be evaporated in a capsule on a water bath, no weighable residue should be left.

Upon treatment of oil of turpentine with hydrochloric acid, and some similarly acting substances, a kind of camphor, closely resembling ordinary camphor, can be produced.

Rosin (*Resina*, U. S., Br.; *Colophonium*, P. G., *Colophony, Common Resin*, or *Rosin*) is defined as the residue left after distilling off the volatile oil from turpentine, and is described as a transparent, amber-colored substance, hard, brittle, pulverizable; fracture glossy and shallowly conchoidal; odor and taste faintly terebinthinate. Specific gravity 1.070–1.080. Soluble in alcohol, ether, and fixed or volatile oils; also in solution of potassium or sodium hydrate. Rosin varies considerably in its appearance, according to the extent of its distillation. If the water with which it was distilled has not been entirely boiled out, it is opaque and yellow; if it contains no water, it is clear; if overheated, it is dark brown or black, if not, it is bright and clear. The abietic acid in the opaque "thus" is a product of hydration of rosin, and may be produced in ordinary rosin by treating with diluted alcohol.

Action and Uses.—Oil of turpentine is one of the most irritating of its series. Applied to the skin and prevented from evaporating, it quickly causes smarting and redness, and after a quarter of an hour or more is liable to destroy the surface and cause ulceration. In large doses, 10 or 15 gm., taken internally, it is a quick irritant, causing prompt action, but is unsafe. Used with suds or other vehicle, as a rectal injection, it is promptly rejected, and in consequence is a useful stimulating evacuant of the lower bowel. Oil of turpentine is readily absorbed in vapor by the lungs, as well as in its liquid condition by the stomach. It is excreted also by the lungs as well as by the skin and kidneys, the latter principally in the course of its elimination; it is, if in large quantity, an irritant to the whole urinary system, causing strangury, frequent micturition, hæmaturia, etc. The urine has a rather pleasant violet-like odor. Like all essential oils it is an antiseptic. In small doses (a few drops) it is stimulant and hæmostatic, and is frequently given with good effect in the hemorrhage of typhoid and phthisis. In large amounts, 2 or 3 gm. and upward, there are mental exhilaration, intoxication; and in poisonous doses dulness, coma, and convulsions, with muscular weakness and heart failure.

The oil is frequently employed as an irritant application (turpentine stupe); a flannel pad wrung out from hot water, and freely sprinkled over the surface with oil of turpentine, acts the same as a mustard paper. It is also a very useful injection (15 gm., in a litre or less of warm soapsuds, and stirred in while being administered). Internally, as above indicated, it may be given in doses of from three to ten drops.

Turpentine itself is not much employed in this country, but may be given for chronic diarrhœa, ulceration of the bowels, chronic rheumatic joints, sciatica, etc., as well as in leucorrhœa and gonorrhœa, under conditions indicating copaiba, over which it probably has no advantages; it may be made into pills and a gram or two be given at a time.

Resin possesses but little activity. It is employed only externally and occasionally.

PREPARATIONS.—Of turpentine there is no official preparation unless the oil and the resin might be so considered. Of the oil we have the *Linimentum Terebinthinæ* or *Turpentine Liniment*, of 65 parts of resin cerate dissolved in 35 parts of the oil. This is a very irritating application. *Resin Cerate* (*Ceratum Resinæ*, U. S.) is made of 35 parts of resin, 15 of yellow wax, and 50 of lard. *Resin Plaster* (*Emplastrum Resinæ*, U. S.) is made of 14 parts of resin, 80 of lead plaster, and 6 of yellow wax. *Cantharides Cerate* (*Ceratum Cantharidis*, U. S.) contains eighteen per cent. of rosin and fifteen per cent. of oil of turpentine.

ALLIED PLANTS AND PRODUCTS.—The genus *Pinus* is the most important of its family and comprises about seventy living species, distributed through the cooler regions of the earth. Turpentines are found to some extent in all species, and they agree closely in their general properties. Similar substances, some of them known commercially as turpentines, are found in related genera. *Venice Turpentine* is the product of *Larix Larix* (L.) Karst. (*Pinus Larix* L.; *Larix Europæa* D.C.) of southern Europe. *Strassburg turpentine* is obtained from *Abies Picea* (L.), Lyons (*Pinus Picea* L.), the European Silver or Strassburg pine. *Pitch*, *Canada* and *Burgundy*, as well as their turpentines, have been considered under those titles. *Tar*, *cade*, and *juniper oils* have also been duly considered. All agree in their general composition and properties with the subject of this article.

Besides these, a number of oleoresins derived from other families (copaiba, Chian turpentine, etc.) are commercial and medicinal products of similar nature.

W. P. Bolles.

TUSCAN SPRINGS or **LICK SPRINGS.**—Tehama County, California.

POST-OFFICE.—Red Bluff. Hotels and cottages.

The Tuscan Springs, about fifty in number, are located about eight miles northwest of Red Bluff, two hundred miles north of San Francisco and one hundred and thirty-five miles north of Sacramento. They cover an area of about ten acres, and are situated at an elevation of 900 feet above the sea-level. No complete analysis seems to have been made, but the waters resemble in medicinal properties those of the Kentucky Blue Lick Springs. A partial analysis of the Red Spring water was made by Dr. F. W. Hatch a number of years ago. It contains: Sulphuric acid,* hydrochloric acid, lime, sodium chloride (20.72 grains per United States gallon), lithia, iodine (4.50 grains per United States gallon), carbonic acid, iron bicarbonate, potassium chloride, magnesia, alumina. Temperature of water, 78° to 80° F.

The White and Black Springs are also in use, but they have not been analyzed. Most, if not all, of the springs contain sulphureted hydrogen in considerable quantities. The temperature of the springs varies from 67° to 94° F. Their action is tonic and alterative, laxative or cathartic, according to the amount taken. Ample facilities for bathing are furnished to guests. There is also a plunge bath thirty by sixty feet, four feet deep at one end, and thirteen feet at the other. The waters have considerable reputation on the Pacific coast in the treatment of syphilitic skin affections, scrofula, rheumatism, liver and kidney troubles. They are used commercially, having a considerable sale on the coast. *James K. Crook.*

* Probably in combination. J. K. C.

TUSCARORA LITHIA SPRING.—Juniata County, Pennsylvania.

POST-OFFICE.—McCoysville.

We are informed by Mr. W. A. Middleton, mineralogist, of Harrisburg, that this valuable lithia water was discovered by prospectors a few years since while boring for oil. The spring flows about four hundred gallons per hour, and is heavily charged with carbonic acid gas. It contains the following solids: Potassium bicarbonate, calcium bicarbonate, lithium bicarbonate, magnesium bicarbonate, magnesium sulphate, sodium sulphate, silica, alumina. The water is of the alkaline class, and is free from nitrates and nitrites. As far as can be learned, the spring is not yet fully developed as a resort, but the water is sold. *James K. Crook.*

TUSSILAGO. See *Coltsfoot.*

TUSSOL—antipyrin mandelate, antipyrin phenyl-glycolate, $C_{11}H_{12}N_2O.C_6H_5.CHOHCOOH$—is a salt of antipyrin which is especially recommended in the treatment of whooping cough. To a baby four weeks old Kennedy gives 0.03 gm. (gr. ss.) twice a day, and to a child of seven years 0.2 gm. (gr. iij) four times a day. Rehn and Blum speak of its efficiency in pertussis, notable change in the cough ensuing in from three to ten days after beginning the treatment. *W. A. Bastedo.*

TYPHOID FEVER.—(τῦφος, smoke; secondarily, stupor.) (Synonyms: English, *Enteric Fever*; German, *Abdominaltyphus*; French, *Dothiénentérie* or *Dothiénenthérite*, or *Fièvre Typhoïde*; Italian, *Tifo Enterico*; Spanish, *Fiebre Continua, Tifo.*)

HISTORY.—There can be no doubt that this disease has prevailed extensively from very remote periods, but its authentic history, like that of so many other infectious diseases, is of quite recent date. Indeed, for this there are especially good reasons in regard to typhoid fever, for the intestinal lesions are the essential and distinguishing characteristics of the disease, and these would be described carefully only after frequent autopsies. Ingenious attempts have been made to associate passages in the works of Hippocrates with this disease, but such have hardly carried conviction to others than their originators. Typhoid fever, as we know it, is not distinctly recognizable in any of these descriptions, and it is not until the seventeenth century that the clinical conditions ending in death, and followed by autopsies revealing intestinal lesions, are to be found in medical literature.

Spigelius, Lancisi, Baglivi in Italy; Friedrich Hoffmann in Germany; Willis, Sydenham, and Huxham in England, all described cases of typhoid fever with such exactness as to leave no doubt of the identity of the disease. Morgagni in France, in the eighteenth century, gave a particularly clear delineation of the course of the disease, and of the intestinal lesions. It still remained, however, for the nineteenth century to define its distinguishing characteristics, and to differentiate typhoid fever from all other diseases.

The Germans are disposed to attribute priority of recognition and determination of the distinctions between typhoid and typhus fevers to Hildenbrand, of Vienna, who published a treatise on "Contagious Typhus" in 1811 (translated into English by Dr. S. D. Gross in 1829). It is true that he distinguished between "contagious typhus" and what he calls "originary typhus," but his ideas about his "originary" typhus were extremely misty, and I think the impartial reader of his treatise will find much difficulty in identifying it with typhoid, although the "contagious" disease answers fairly well to typhus fever.

Bretonneau, Petit and Serres, Louis and Chomel in France, during the first thirty years of this century, did more, by their careful observations at the bedside and their patient labors in the autopsy room, to elucidate the symptoms and course of the disease, to connect these with the pathological lesions, and to place the whole in the clear light by which we regard this very important disease to-day, than any or all of their predecessors. Even after the publication of their observations a good deal of confusion prevailed for another ten years between typhoid and typhus fevers, the one being more common in France, the other in England, the symptoms being by no means very dissimilar in exceptional cases, or at least sufficiently alike to throw doubt upon the recently promulgated pathology.

This doubt it was the privilege of American pupils of Louis to be instrumental in dispelling. James Jackson, Jr., of Boston, published in 1830, 1833, 1834, personal observations confirming the occurrence of intestinal lesions as the result of typhoid fever. Gerhard, of Philadelphia, in 1835, reported cases of typhus fever occurring during an epidemic at the Philadelphia Almshouse, which marked out plainly the characteristics of that disease; and in 1837, in association with Pennock, Gerhard established clearly the fact that typhoid and typhus were distinct diseases. This was further brought out the following year (1838) in Paris, and in 1840 in this country, by George C. Shattuck, of Boston, as the result of observations in the London Fever Hospital, at the request of and following the teaching of Louis. Stillé, of Philadelphia, who had previously been under Gerhard at the Philadelphia Hospital during the typhus epidemic, and who was in Paris at the same time with Shattuck, was also instrumental in establishing before the Société Médicale d'Observation the anatomical and clinical distinctions between the two diseases.

As a result of these and subsequent studies and reports, the non-identity of typhoid and typhus fever was early recognized and accepted in the United States—earlier and more generally than in England. Dr. A. P. Stewart, of Glasgow, who, after studying fevers in the Fever Hospital of that place, resorted to Paris for the same purpose, accurately described the chief features of these two diseases before one of the Paris medical societies, in 1840, and was the first of his countrymen who did so. It was not, however, until ten years later (1849–51) that a general recognition of the quality of the two diseases, of their specific characteristics, was enforced in Great Britain by the authority of Sir William Jenner. Since that time typhoid fever has been everywhere accepted as a distinct morbid entity, and all difference of opinion as to its special characteristics may be said to have disappeared.

Etiology.—No sooner were the problems of the semeiology and pathology settled, and the conclusions generally accepted, than the equally important question of the etiology of typhoid fever took their place, and a discussion arose which lasted thirty years. The medical world divided into two parties: (*a*) those who held that typhoid fever is not only a distinct disease, but a specific disease having a specific poison, which is only produced by itself, and only reproduces itself; (*b*) those who though acknowledging its distinct symptomatology and pathology, still held that it at times arises autochthonously or spontaneously; that mere filth, or according to some who embraced this view, even depressing emotions which derange the digestion, may give rise to these special results. These two theories were propounded and actively supported by Drs. Budd and Murchison, respectively, and from the year 1850 were largely identified with their names. Both of these theories were of practical benefit, for it was largely due to the efforts of Murchison that the foundations of modern hygiene were instituted, and the influence of Budd was felt both in the care of the patient and his excreta and in the incentive to determine the specific poison. As early as 1871 attempts were made to identify definite organisms as constantly occurring with the disease, but not until 1880 was the germ discovered by Eberth, which has since been found to answer the requirements of a specific organism.

The Eberth-Gaffky bacillus, or bacillus typhosus, was of constant occurrence in typhoid fever and absent in health. It was finally isolated, and after much experimentation grown in pure culture. Owing to the apparent insusceptibility of animals to the disease all attempts at inoculation of animals with typhoid have been unsuccessful, though lately Remlinger has claimed to have caused the disease in rabbits, but his work has not yet been confirmed. The organism has, however, been accepted. Its viability in the human body, before and after death, and its duration in different media, liquid and solid, under varying conditions of heat and cold, have been more or less definitely determined.

It is a short, thick rod, about three times as long as wide, and with rounded ends. The length equals one-third the diameter of a red blood corpuscle. It is somewhat variable under different conditions, and may be thicker or thinner according to circumstances, and may become arranged end to end, forming threads. In hanging drop it has motility due to numerous flagella, which may be seen by careful staining. The other characteristics and growth under different conditions belong to bacteriology and need not be discussed here. It is of practical importance, however, to know that these bacilli may live indefinitely under favoring circumstances, and they have been shown experimentally to exist as long as three months in milk, water, and in a dead body, and five and one half months in soil, and to resist freezing, though they succumb quickly to a temperature of 167° F. The practical value of these facts will appear.

By this discovery of the bacillus typhosus by Eberth in 1880 the etiology has been placed upon a definite basis.

Predisposing Causes.—Age. This is the most important of the predisposing causes. It is essentially a disease of youth, the great majority of cases occurring between fifteen and thirty years of age, and this holds true in general of all countries. Statistics on this and other points are generally made up from hospital patients, but would probably not vary much as to age if applied to those treated at home. Murchison deals with the largest figures, extending over a period of twenty-three years at the London Fever Hospital. He states that persons under thirty years of age are more than four times as liable to typhoid fever as persons over thirty. Of 5,911 cases admitted to the London Fever Hospital, between the years 1848–70 (twenty-three years), 56.70 per cent., more than one-half, were between fifteen and thirty years of age; 28.58 per cent., more than one-fourth, were under fifteen; 13.30 per cent. were over thirty; while only 1 in 71 cases exceeded fifty. The contrast between typhoid and typhus fevers in this respect is shown by the same tables, only 24.87 of the typhoid cases being over twenty-five years of age during a period of years when 50.66 per cent. of the typhus cases were over that age.

For five years preceding 1870 in Berlin, Zuelzer reports the following table of cases of typhoid among every 10,000 inhabitants of all classes:

From 8 to 10 years of age.....	18	From 35 to 40 years of age.....	13
" 10 to 15 " " ".....	22	" 40 to 45 " " ".....	16
" 15 to 20 " " ".....	32	" 45 to 50 " " ".....	13
" 20 to 25 " " ".....	31	" 50 to 55 " " ".....	27
" 25 to 30 " " ".....	20	" 55 to 60 " " ".....	7
" 30 to 35 " " ".....	11	" 60 to 65 " " ".....	10

This table gives the usual ratio up to thirty years, but betrays some singular discrepancies in the later years. Liebermeister found that seventy-seven per cent. of the typhoid patients in the hospital at Basle, from 1865 to 1870—a period of five years—were between fifteen and thirty years of age; and Fiedler reported that in Dresden eighty-one per cent. of all the typhoid patients were between those ages.

The average age of 291 cases which occurred at the Massachusetts General Hospital was about twenty-two years. Other statistics in this country are of the same tenor.

It should not be forgotten that typhoid fever does occasionally occur in the aged, and by no means infrequently in the very young. Undoubted cases in infants under a year old are on record. In fact, recent investigation tends to show that typhoid fever in infants is much more common than is generally acknowledged. Even in the fœtus undoubted cases of typhoid fever have been recognized. In these cases the mothers were suffering from the disease, and the infection probably took place through injury or infarct in the placenta, which was in some cases demonstrable. Some of these fœtal cases near term had fever, diarrhœa, and positive Widal reaction, and some showed at autopsy ulcerated Peyer's patches, enlarged spleen, and typhoid bacilli were found in the organs. A considerable number of cases of very probable typhoid fever in the first, second, and third years of life has also been collected. Griffith and Ostheimer have collected 139 cases in the first year, 187 in the second, and 325 in the third. Many of these cases had positive Widal reaction, and in some typhoid bacilli were found post mortem. The symptoms often are so little marked in the very young that the nature of the trouble is liable to be overlooked. Subsequent immunity to exposure, it is fair to suppose, is sometimes due to an early unrecognized attack. The susceptibility is greatest between the ages of fifteen and twenty-five; next between ten and fifteen; and next between twenty-five and thirty.

Sex: If guided by hospital statistics, one would conclude that the disease is somewhat more common among men than among women. On the other hand, men are more likely to resort to hospital treatment, and the difference may perhaps be explained in this way. As a fact, either sex is probably about equally liable.

Locality: Typhoid fever is no respecter of locality, although having its places of predilection. It prevails alike in cities, in towns, in villages, in hamlets, and in solitary houses; among the poor and the well-to-do; on high and on low ground; over a sandy or over a clayey soil. It is, perhaps, of all infectious diseases, the most constantly to be found, under the greatest variety of conditions.

Seasons of the year: In all countries of the northern temperate zone the last six months of the year, from July to December, are those in which typhoid fever is most prevalent, and in the southern temperate zone the corresponding months, from February to July, are similarly prominent. September, October, and November are three months in which the largest number of cases occur, as shown by tables from various localities.

A statement of the deaths from typhoid occurring in Basle during fifty years gives the following for the different months. January, 192; February, 143; March, 137; April, 121; May, 160; June, 169; July, 186; August, 202; September, 237; October, 237; November, 236; December, 193.

Murchison's 5,988 cases at the London Fever Hospital, during twenty-three years, were distributed through the different months as follows: January, 433; February, 306; March, 318; April, 209; May, 232; June, 335; July, 431; August, 721; September, 803; October, 839; November, 819; December, 539—27.7 per cent. of the entire number were admitted in the two months of October and November, and only 7.3 per cent. in the two months of April and May.

Of 621 cases treated at the Pennsylvania Hospital during ten years, 89 were admitted during spring, 259 during summer, 182 during autumn, and 91 during winter. So marked is the prevalence of typhoid in the months of September, October, and November that it is often spoken of popularly as "fall" or "autumnal" fever. Owing to exceptional causes, epidemics may occur at other seasons of the year. In the older cities the disease has a tendency to become endemic, and to last through the winter months.

Notwithstanding that typhoid fever is more prevalent in the autumn months, statistics show that the mortality is much greater in the first quarter or first half of the calendar year. The reason of this greater mortality in the spring is probably not that the infection is more virulent at that season, but that human vitality is probably lower, and fatal complications are more frequent. The fallacy of statistics must also be remembered, and the fact that there are so many mild cases in the autumn would naturally lower the mortality rate.

Moisture and temperature, level of ground water: These do not seem to have any constant relation to the prevalence of typhoid. It is found to be active during and after both cold and hot seasons, dry and damp weather, although it is said that a warm, dry summer favors abundant typhoid in the autumn. Murchison regards warmth, with moisture and but little rain, as the most favorable combination of circumstances. Von Pettenkofer and Buhl succeeded in establishing a relation between low ground water and increasing typhoid for a time at Munich, but this does not hold good for other places and other countries. Such a connection is far from being invariable for every year and for all places. Wet seasons as well as dry, are followed by, and coincide with, abundant typhoid. In Berlin it has been shown that the inhabitants most exposed to the influences of the ground air are not those most affected by the disease.

In this connection Sedgwick's and Winslow's very recent and thorough statistical studies on seasonal variations in temperature and on the prevalence of typhoid fever in various countries deserve notice. These investigators have brought together statistics of the monthly variations in temperature and in the prevalence of typhoid fever for thirty communities, representing four continents and both hemispheres, and a very wide range of climate. While not asserting that the typhoid bacillus multiplies in the environment during the summer months of a temperate climate, they do consider that it is the absence of the destructive influence of cold, rather than any stimulating influence of heat, which permits the rise culminating in the autumnal maximum. They postulate their conception of the probable mechanism of the seasonal changes as follows:

The bacteriology and etiology of typhoid fever both indicate that its causal agents cannot be abundant in the environment during the colder season of the year. The germs of the disease are carried over the winter in the bodies of a few patients, and perhaps in vaults or other deposits of organic matter where they are protected from the severity of the season. The number of persons who receive infection from the discharge of these winter cases will depend, other things being equal, upon the length of time during which the bacteria cast in these discharges into the environment remain alive and virulent. The length of the period during which the microbes live will depend largely upon the general temperature; as the season grows milder, more and more of each crop of germs sent at random into the outer world will survive long enough to gain entry to a human being and bear fruit. The process will be cumulative. Each case will cause more secondary cases; and each of the latter will have a still more extensive opportunity for widespread damage. In our opinion the most reasonable explanation of the seasonal variations of typhoid fever is a direct effect of temperature upon the persistence in nature of germs which proceed from previous victims of the disease.

Individual idiosyncrasy plays a part as a predisposing cause in this as in other infectious disorders. Some persons and some families seem proof against the poison, even in an active form, while others contract the disease upon slight provocation. An inherited predisposition has sometimes been suspected as reappearing through several generations. Notwithstanding the immunity usually conferred by one attack, some persons have been known to pass through several distinct attacks at different periods. Phthisis, pregnancy, and lactation have been supposed to confer some degree of immunity, but this is doubtful.

The robust are quite as likely to be attacked as the feeble, and in the opinion of some are even more prone. Intemperance, fatigue, and mental emotions can only be admitted as predisposing causes very indirectly.

Exciting Causes.—Since the identification of the specific micro organism causing the definite disease, typhoid fever, the etiology in relation to exciting causes has to do principally with the mode of entrance of the bacilli into the human economy.

Because the bacilli are capable of resisting drying to a certain extent, and may therefore be blown about in the air, the possibility that they may gain entrance through the respiratory organs cannot be ruled out, though this is probably infrequent, and even then some of the organisms could also be swallowed. Dr. Eduardo Germano concludes from experiments that typhoid bacilli cannot resist thorough drying, and therefore cannot be transmitted by air currents through dust to man. Undoubtedly the commonest mode of entry is by ingestion. Formerly it was supposed that water was the only vehicle of practical importance. That it was frequently the means of infection was so satisfactorily proved and is so generally recognized that it need only be mentioned, and space need not be occupied by the now familiar details of convincing instances, the latest and one of the most unfortunate of which is that at Ithaca, N. Y., the home of a university supporting scientific departments and a medical school.

It may not, however, be generally realized, even by physicians, who recognize typhoid fever as largely a water-borne disease, that the death rate from typhoid fever has declined steadily in direct ratio to the introduction of well-managed public water supplies, or to what extent this has taken place. Massachusetts may be taken as an example, for in that State the provision for public water supplies has reached its highest development in this country—over ninety per cent. of the population being now supplied with water under public control. The number of deaths from typhoid fever in Massachusetts in 1901 was smaller than in any single year since the beginning of registration in 1842, and at that time the population of the whole State was about equivalent to that of Boston and its suburbs today. The death-rate percentage from this disease in 1901 in thirty-three Massachusetts cities was only one-fourth of what it was in these same cities thirty years ago. In 1865 only twenty-five per cent. of the population used public water, and the death rate from typhoid at that time was 92.9 per 100,000 inhabitants. In 1875 forty-one per cent. of the population had public water and the death rate had decreased to 80 per 100,000. In 1901 over ninety per cent. of the people were supplied from public water systems, and the death rate from typhoid had fallen to 19.5 per 100,000 inhabitants.

Milk.—Epidemics due to milk have also been thoroughly traced. Sometimes the infected milk has been contaminated by polluted water which was used in washing the vessels or in diluting the milk. In some cases the milk was directly infected by those who were sick or assisting in the care of the sick and at the same time doing dairy work.

Kober recently has tabulated 195 epidemics of milk-typhoid. In 148 of these epidemics there is evidence of the disease having prevailed at the farm or dairy; in 67 instances it is probable that the infection reached the milk by soakage of the germs into the well water, with which the utensils were washed, and in 16 instances the intentional dilution with polluted water is a matter of evidence. More recently butter, fruit, fresh vegetables, and salads, which may have been moistened with infected water, have been shown to be the starting-points of epidemics.

Oysters and Shell Fish.—Shell fish are another source of infection, especially oysters which have been fed or fattened in contaminated beds. In 1894, at Wesleyan College in Middletown, Conn., many students who ate raw oysters were affected with typhoid fever, while those who ate them cooked escaped. It was found that the oysters had been temporarily kept in fresh water contaminated by sewage containing also the discharges of typhoid patients. This outbreak was worked out with much care by H. W. Conn, professor of biology at Wesleyan, for the seventeenth annual report of the Connecticut State Board of Health. The details are very convincing, and leave no reasonable doubt as to the relation of cause and effect between the oysters and the typhoid fever. Other authentic cases have been published, and in some instances the typhoid bacilli have been found in the oysters. As a rule, undoubtedly, the oyster or mollusk is simply a common carrier, the passive, indifferent vehicle or intermediary between the contaminated water and the human organism. It has been demonstrated (Foote) that typhoid cultures introduced within the shells of oysters and kept at 57° F. give active organisms at the end of a month.

Drs. Morny and Bulstrode have presented elaborate reports on the relation of shell fish and oysters to disease to the French Government and to the English Local Government Board respectively.

Dr. Fraser, medical officer of health of Portsmouth, England, where outbreaks of typhoid fever traceable to oysters have occurred, suggests the following propositions [1] as essential to establish proof against the oyster:

1. That the oysters had been eaten at such a date previous to the onset of the disease as would be consistent with what we know as to the time typhoid fever takes to develop in man.

2. That there was no other condition common to all or a large proportion of the cases which could be regarded as playing a causal part in the disease.

3. That the oysters had not only been exposed to sewage contamination, but that this sewage actually contained the specific infection of typhoid fever.

Ice.—Ice has at times been suspected and accused of harboring and conveying the typhoid-fever poison. Sedgwick and Winslow have recently published very elaborate investigations and experiments as to the effect of cold upon the bacilli of typhoid fever. Without going into details, their conclusions may be briefly stated, both because they are the result of careful work and because they are reassuring. Moreover, they harmonize with previous work done by the Massachusetts State Board of Health. Exceptionally, artificial ice made from impure water and used quickly after manufacture may conceivably be a menace to the public health. In the same way natural ice, if increased in thickness by cutting holes and flooding, and if served within a week or two, might allow sufficient of the virus to persist to excite the disease. Yet such instances must be very exceptional; and the general result of human experience, the absence of epidemics of typhoid fever traced conclusively to ice, the fact that cities like New York, and Lowell and Lawrence in Massachusetts, have used the ice of polluted streams, and have yet maintained low death rates from typhoid fever, all tend to support the conclusion that natural ice can very rarely be a vehicle of typhoid fever.

The following are the conclusions of the Massachusetts State Board of Health on this subject as given in its annual report for 1889:

"While clear ice from polluted sources may contain so small a percentage of the impurities of the source that it may not be regarded as injurious to health, the snow ice and any ice, however clear, that may have been formed by flooding, is likely to contain so large a percentage of the impurities of the source, and with these impurities some of the disease germs that may be in the source, that the board feels bound to warn the public against using ice for domestic purposes that is obtained from a source polluted by sewage beyond that which would be allowable in a drinking-water stream or pond; and that, in general, it is much safer to use for drinking-water and for placing in contact with food that portion of the ice that is clear."

In 1898 and 1901 the Boston Board of Health conducted, through Dr. H. W. Hill, investigations of the Boston ice supply with especial reference to danger from typhoid fever.

The conclusions arrived at practically accord with those of the State Board and with those of Sedgwick and

[1] Brit. Food Journ., January, 1903, p. 4.

Winslow, and are thus summed up: "On theoretical grounds the danger of infection from ice is very small. Practically, and under the conditions of the present Boston supply, danger of infection through natural or artificial ice is almost *nil*. . . . Careful search of the records has shown that but one presumably authentic case of transmission of typhoid fever through ice is on record. The fact that there is such a case shows the possibility of such infection; the fact that there is only one shows its extreme rarity."

Notwithstanding the experiments and conclusions of the authorities previously quoted, Drs. Hutchings and Wheeler of the St. Lawrence State Hospital at Ogdensburg, N. Y., have since, and very recently, reported an epidemic of typhoid fever due to infected, clear ice which involved thirty-nine inmates of that institution. It is scarcely possible to impugn the accuracy of the details or the conclusions of this report.

Flies.—That flies may carry the contagion is proved by finding the bacilli on different parts of their bodies, but

Cases of less than a week's incubation are open to suspicion, and those reported instances in which immediate illness has followed the sudden opening of drains, etc., are probably, in their inception at least, due to septic or miasmatic poisoning. On the other hand, the instances of very long incubations, over four weeks, are but little better authenticated. The number of cases with a period of incubation not included between ten days and three weeks is probably small.

During this period the patient is able, as a rule, to pursue his ordinary occupations, though generally with less vigor, and there is apt to be diminished appetite.

Period of Invasion.—This stage begins with the first feelings of malaise, which are often accompanied by a chill or chills. There are headache, dulness, and listlessness, general soreness and chilliness, sometimes epistaxis, often diarrhœa, sometimes moderate abdominal tympanites, with tenderness and gurgling in the right iliac fossa, and the tongue presents a thin, whitish coat, not extending to the tip and edges, which may be rather red.

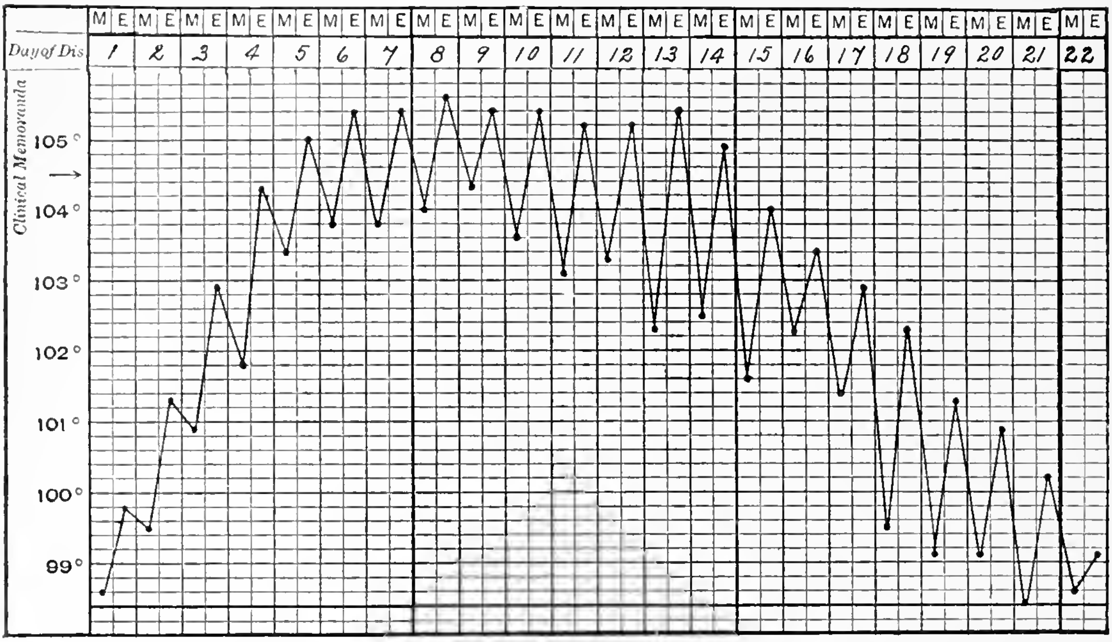

FIG. 4886.—Temperature in a Typical Mild Case of Typhoid Fever from First Day of Attack. (After Wunderlich.)

whether in sufficient quantity to be of grave importance in the dissemination of typhoid fever in civil life is still a somewhat open question. That sporadic cases have such an origin probably must be admitted, and this may have some influence upon the seasonal variations of typhoid.

All of these modes of infection have their practical importance in teaching the care of the patient and the prevention of the spread of the disease. Contamination of any article of food by those caring for typhoid patients is a constant source of danger, which, however, can generally be prevented by caution.

COURSE OF THE DISEASE.—*Incubation.*—The period of incubation, as with other infectious diseases, is a variable one, and probably depends as much on the susceptibility of the individual, as shown in idiosyncrasy or constitutional condition, as on the concentration and activity of the poison. From hospital patients it is difficult to draw any conclusions of value, either as to the period of incubation or as to the duration of the disease. But cases have been recorded in which there is little room for error as to the time of invasion, and from which maximum, minimum and average periods may be fixed in a general way.

All or only some of these symptoms may be present, but are hardly pathognomonic, as many of them may be present in the early stage of other febrile affections. In the temperature, however, we find an important aid to diagnosis.

If, in addition to the above systemic symptoms, the temperature rises step-like steadily from day to day, and from morning to evening, and reaches from 103° to 104° F. by the fourth day, there will be less reason to hesitate as to the diagnosis. By this time the fæcal discharges will begin to exhibit the characteristic light-yellow color and pea-soup consistence. By the end of the first week the temperature will have reached the maximum point which it is likely to hold during the disease, and the *stage of invasion* may be considered to be at an end.

Second Week.—From the end of the first week the temperature pursues a fairly steady course from the highest point, rising from morning to evening, and falling from evening to morning, from 1° to 2.5° F., the chart developing the characteristic zigzag appearance; the countenance becomes more dull; the eyes more suffused; the face more flushed; the tongue more coated; the intestinal discharges thinner and more frequent; the abdominal tenderness and tympanites more marked; the skin drier, congested, and showing evidence of paresis of the vaso-motor nerves in the ready production of Trousseau's *taches cérébrales;* both skin and breath exhale a peculiar odor; the pulse increases in frequency—rising, perhaps, from between 80 and 100 to between 100 and 120—and is more in proportion to the temperature; the characteristic rose spots—small pink papules the size of a pin's head, slightly elevated above the surface and disappearing upon pressure—present themselves upon the abdomen and back; scattered sibilant râles are heard over the chest; the splenic area is enlarged; the urine is diminished in quantity, high-colored, slightly albuminous; a mild form of delirium or of coma vigil is developed. With these conditions the end of the second week will be reached.

Third Week.—At this stage the remissions in temperature from evening to morning will begin to be somewhat more marked, and the morning temperatures a little lower from day to day; the pulse and respirations, however, keep up their former frequency and may be even more rapid; the pulse is softer and weaker, and is apt to exhibit a slight dicrotism, due to the diminished tension of the arterial walls; the tongue is dry, brown down the centre and red at the tip and edges; the teeth are covered with sordes. The frequency of the alvine discharges presently begins to diminish, and the consistency to improve. The patient, however, exhibits the exhausting effect of the disease more than in the previous week; he lies generally upon his back, and presents a dull, stupid appearance, from which he can usually be easily roused; muscular tremor is shown upon attempts to move, speech and the protrusion of the tongue are attended with slowness and hesitation; a smart tap upon one of the large muscles is followed by a swelling due to the contraction of the degenerated muscular fibres, the heart sounds are feeble; the emaciation is pronounced; the rose spots begin to disappear. This brings the disease to the end of the third week.

Fourth Week.—About the end of the third week, or within a few days thereafter, the temperature will touch normal in the morning, although there will be a difference of from 2° to 4° F. between the morning and evening temperatures; the pulse and respirations will diminish in frequency, the former falling from between 120 and 100 to between 100 and 80, at the same time improving in character; the sibilant râles in the lungs and the signs of hypostatic congestion—if such have existed—will gradually disappear; the tongue will begin to clear and to become moist at the tip and edges; the dejections, from having been five or six in the twenty-four hours, and perhaps at times passed in bed involuntarily, will not occur oftener than once or twice in that time, or even in forty-eight hours; they will also begin to be more formed. The signs of nervous exhaustion are less striking, and the patient begins to enjoy hours of quiet, natural sleep.

By the end of the fourth week further progress is made in this direction; the temperature varies but little from normal either morning or evening; the pulse finds the level of health; the tongue is clean and moist, and the patient may be fairly pronounced a convalescent.

Such is the course of a typical case of typhoid fever of average severity, treated on the so-called "expectant" plan, ending in recovery; but individual cases vary from this in an infinite number of ways. In fact, there is no disease presenting a more diversified picture clinically. Any of the above symptoms may be exaggerated or absent altogether. The patient may not take to his bed at all, as in the so-called ambulatory typhoid; the period of convalescence may supervene rapidly upon a febrile course of not more than ten days or two weeks; and, on the other hand, instead of terminating in three weeks the pyrexia may continue for five or six weeks, or even much longer, and that without any genuine relapse. Some authorities used to explain these variations in duration by the statement that we have in typhoid two forms of fever to deal with—a primary, due to the infection of the

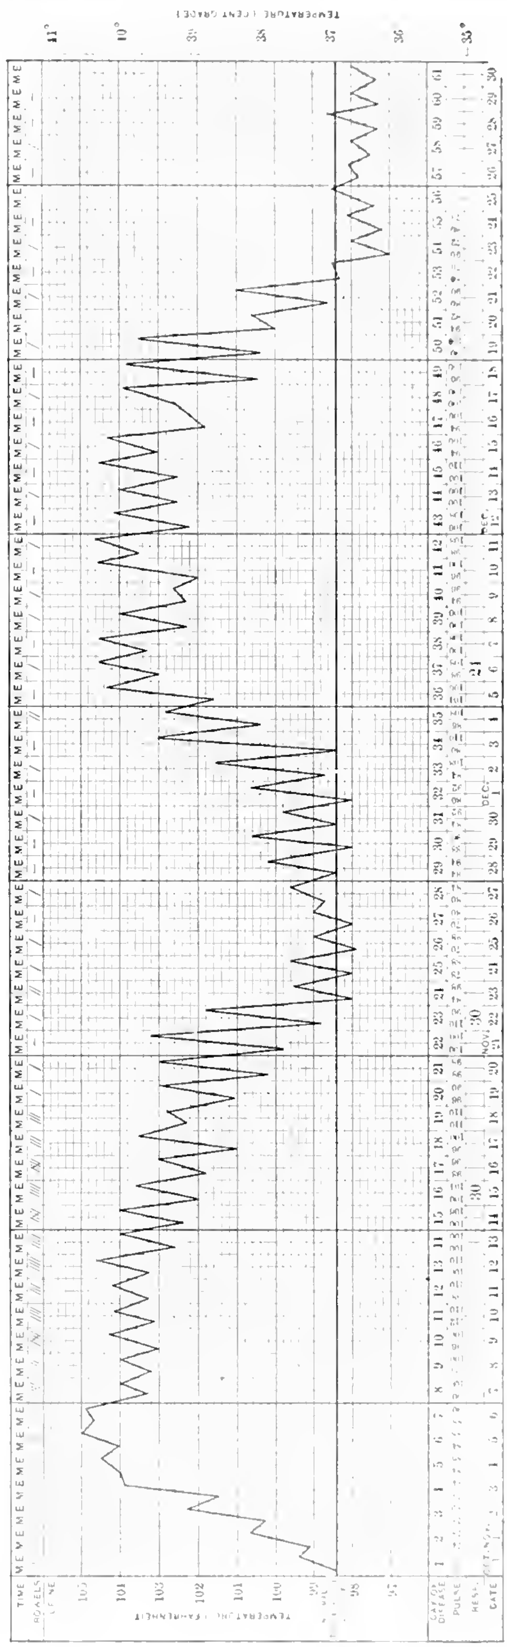

FIG. 1867. Temperature in a Somewhat More Severe Case of the Disease, with Relapse. (From the author's own experience.)

system by the typhoid poison, and a secondary, caused by the gangrene and ulceration of the intestine, and consequent septicæmia. Delirium, again, instead of being of a mild, stupid type, may be very active and acute, the patient requiring watching to prevent his getting out of bed or jumping from a window.

Diagnosis.—The diagnosis in a typical case of typhoid fever is comparatively easy. The gradual onset, with backache, headache, loss of appetite, and general malaise, occasionally with chills and vomiting, with gradually increasing rise of temperature, and frequently a progressive apathy, in conjunction with flushed face, dry tongue, and often an early enlarged spleen, and early rose spots, make a picture which is very characteristic of the disease. There is, however, as has been already stated, every variation in these symptoms, and sometimes the evidence is so slight that diagnosis is very difficult. In these cases certain laboratory tests may make the diagnosis possible.

Leucocytosis.—The leucocyte count is of somewhat negative value, as in typhoid fever, uncomplicated by any inflammatory process, the leucocyte count is usually normal or may be less than normal. It is apt to become less during the acute stage of the disease, and may become high on the advent of any suppurative process. For this reason a leucocyte count early in the disease may be of great relative value and should always be done as a routine measure.

Widal Reaction.—The Widal reaction was discovered in 1896 from the converse of the theory that certain organisms could be identified by their agglutinating under the action of serum from animals immunized to their influence. If, then, the serum had this effect on identified organisms, it would probably be from an immunized animal. This was found to be true in a large percentage of typhoid-fever patients, and the test is now applied as a routine in all hospital and many private cases, and should be in all cases.

The most practical way of applying the test is as follows: From a bouillon pure culture of typhoid bacilli with a sterilized platinum loop take ten drops, place this fluid on a clean slide and cover with a cover glass. On another slide place ten more loopfuls of the culture and one loopful of the suspected serum and stir well. On still another slide place five or ten more loopfuls of this culture and one loopful from the second slide, and mix thoroughly. This gives for examination one specimen of the typhoid culture for a control, one of suspected serum diluting the culture 1 to 10, and the third diluting the serum 1 to 50 or 1 to 100, according as five or ten drops are used on the third slide. These three preparations may be made with care on different parts of the same slide. The first two of these preparations are watched occasionally under the microscope, and if in fifteen minutes, or at most within half an hour, the bacilli in the second specimen lose their motility and become clumped together in numerous colonies, the reaction is presumably positive. This process should occur also in greater dilution, and for this purpose the third preparation should also be examined if clumping has occurred in the second.

The clinical importance of the Widal reaction as a pathognomonic sign of typhoid fever is very great in spite of some of its disadvantages. In the best statistics from very large numbers of cases a positive Widal reaction has been obtained in over ninety-five per cent. In some of these series of cases the reaction is present in ninety-nine per cent. In diseases other than typhoid the reaction is obtained in less than two per cent., and probably with the more proper high dilution (1 to 50) this proportion would be still less. From the blood of some cases resembling typhoid fever with persistent negative Widal reaction organisms, called paracolon bacilli, closely allied to Eberth's bacillus, have been isolated, and with cultures of these organisms an agglutination reaction has been obtained from the serum from the patient. It is possible that other similar organisms exist, and probably when they are identified a positive serum reaction will be obtained in a still larger proportion of cases.

The principal disadvantage of the Widal reaction is that it does not usually occur early in the disease. Though it has been found as early as the third day, it occurs in the first week in only about twenty-five per cent. of the cases. In the majority of cases it is present in the second week, but it may be much delayed, perhaps occurring during a relapse or convalescence as late even as the sixtieth day.

Diazo Reaction.—The diazo reaction, suggested by Ehrlich in 1882, may be of some help in the diagnosis of typhoid fever. A small quantity of the patient's urine is mixed thoroughly with an equal quantity of a freshly prepared solution containing one part of a one-half-per-cent. solution of sodium nitrite and fifty parts of a saturated solution of sulphanilic acid (2 gm.) in hydrochloric acid (50–1,000 c.c. water). This mixture is then made alkaline with ammonia, and if the diazo reaction is present, the solution and foam become carmine red, otherwise they are brownish-yellow. This reaction occurs usually early in typhoid fever, often before rose spots or the Widal reaction. It also usually disappears early in the defervescence and may reappear in relapse, but not in recurrence of fever due to other causes. The objections to this test as a diagnostic aid are that it does not occur in ten per cent. or more of the cases, and it may occur also in tuberculosis, typhus, pneumonia, and acute exanthemata, especially measles.

Other laboratory aids in diagnosis, which are, however, at present of somewhat less practical value, are the obtaining of typhoid bacilli in cultures from the stools, urine, sputum, blood, and rose spots. They may be obtained very early from the stools, and in pure culture from the urine, blood, and rose spots before a positive Widal reaction is present, but the technique of these procedures makes them as yet somewhat difficult of general application.

Differential Diagnosis.—In differentiating typhoid fever of a more or less atypical form, or with misleading complications, the laboratory aids to diagnosis may be very helpful. The leucocyte count may serve to distinguish cerebro-spinal meningitis and pneumonia, and an examination of the blood may show a malarial parasite. The disease from which it is most difficult to distinguish typhoid fever is acute miliary tuberculosis. The absence of remittency in the fever and the presence of rose spots are the most characteristic evidence of typhoid fever, but in the absence of a positive Widal reaction, if the bacilli were cultivated from the stools, urine, or blood, the diagnosis would be certain. Tubercle bacilli may be demonstrated in the blood or may be obtained from the sputum. The two affections have been found together.

Paratyphoid is referred to already in connection with the paracolon group of bacilli, and is described elsewhere.

Anatomical Lesions, Morbid Anatomy, Pathology.—For a complete description of the various pathological lesions, and they are numerous—such as parenchymatous degeneration, cloudy swelling of the vital organs, fatty degeneration of the substance of the heart, hypostatic congestion of the lungs, ulcerations of the larynx and œsophagus, enlargement of the spleen, thrombosis, abscesses, diphtheritic affections, etc.—common to typhoid fever and other wasting febrile diseases, the larger treatises should be consulted. The changes in the intestinal glands, and especially in the solitary and agminated glands (Peyer's patches) of the ileum, constitute the characteristic lesions of typhoid fever; these are invariably present, and in the later stages are peculiar to this disease; they are generally most pronounced in the neighborhood of the ileo-cæcal valve, the patches being most numerous in this part of the ileum. The process may extend to the solitary glands in the large intestine. The individual glands forming a Peyer's patch number from one to four hundred, and give the mucous membrane in health an unequal and roughened appearance. The patches are elliptical, situated on the free borders of the intestine opposite the insertion of the mesentery, their long diameter being parallel with the longitudinal axis of the intestine. They number from thirty upward, are confined to the small intestine, and, as before said, are most numerous and least scattered in its lower third.

These glandular lesions are usually described as passing through four stages: (1) The stage of swelling and

FIG. 4808.—Peyer's Patch and Solitary Lymph Nodules. Peyer's patch shows marked swelling with some loss of surface due to necrosis and beginning ulceration. (From Mallory.)

hyperplasia of the intestinal and mesenteric glands; (2) necrosis and sloughing; (3) ulcerations; (4) healing. In general terms, it may be said that during the *first week* the glands become gradually enlarged and the mucous membrane undergoes the usual changes of catarrhal inflammation; during the *second week* necrosis of the superficies of the glands sets in; during the *third week* there is sloughing of the necrosed glandular tissue, forming ulcers which from the end of the third week begin to clean, and then pass on to the stage of healing. At whatever period of the disease a patient dies, some of the intestinal glands will generally be found in the first stage, and at most autopsies some will be found in the first three stages. The process less often passes on to the second and third stages in the solitary glands.

Since the discovery in 1880 of the specific micro-organism causing typhoid fever, this bacillus has been demonstrated as occurring in every part of the body of patients dying with this disease, viz., the heart's blood, the lymphatic system, the bile, rose spots, etc. In fact, it has been demonstrated in life occurring in the blood, in the urine, in sputum, and in rose spots. Thus from one point of view typhoid fever may be regarded as a systemic affection; but the mode of entry is by ingestion, and the most important and the characteristic lesions are those of the intestine and mesenteric lymph nodes. Though there have been a number of cases of typhoid fever reported in which the diagnosis was made bacteriologically and clinically, but in which no intestinal lesions were found, yet it cannot be proved that no such lesions had existed.

By a series of very early autopsies at different stages of the disease, Mallory showed in 1898 (and his work has since been confirmed by others) that the lesions are due to the action of the diffusible toxin of the typhoid bacillus, which causes a proliferation of the endothelial cells of the lymphoid tissue, lymphatics and blood-vessels of the intestine, of the mesenteric lymph nodes, and of the liver and spleen, and to some extent of other organs. The cells become phagocytic and include lymphoid cells and red blood corpuscles. They lead to necroses in the intestine, mesenteric lymph nodes, liver and spleen, and occasionally other organs, by blocking up the blood-vessels and capillaries.

Necrosis and Sloughing.—The hyperplasia of the lymph cells having reached a certain degree, resolution is impeded, the vessels become choked, an anæmic necrosis or venous thrombosis is induced, a slough forms, which must be separated and thrown off. This process may be superficial, affecting only the mucous tissue or even only a part of this; or it may be, and usually is, deeper, extending to and involving the submucosa. It is always more intense toward the ileo-cæcal valve. The solitary glands may be capped with small sloughs. They have a yellowish-brown color from the bile pigments. The depth to which the necrosis extends depends on the intensity of the lymphoid infiltration; it may be deep in the muscular coat, and even reach the serosa, when perforation becomes imminent. The retrograde process advances more rapidly in the follicles than in the interfollicular tissue, and pigment is deposited in the depressions thus formed.

Ulceration.—The separation of the sloughs is gradually effected from the edges inward, and entails among other

FIG. 4809.—Peyer's Patch and Solitary Lymph Nodules just below Ileo-cæcal Valve. Appendix is curled around the lower end. Shows same condition as Fig. 4808. (From Mallory.)

dangers that of opening blood-vessels and perforation of the coats of the bowel. The size of the ulcer is directly proportionate to the depth and extent of the necrosis. The entire thickness of the mucosa may not be affected, and small, shallow losses of substance may frequently be seen in swollen patches. Generally the slough, in separating, exposes the submucosa and muscular coat, particularly the latter, which forms the floor of a large majority of typhoid ulcers. It is unusual for an entire

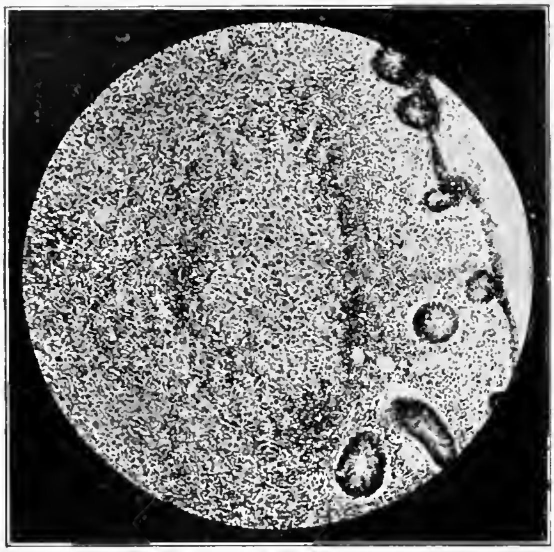

FIG. 4810.—Lymph Nodule in a Peyer's Patch showing the Presence of great Numbers of Phagocytic Cells which have replaced nearly all of the Lymphoid Cells. (From Mallory.)

patch to slough out, and the perfectly ovoid ulcer opposite the mesenteric attachment is rare. More commonly the sloughing commences in different portions of a patch, and small irregular losses of substance result, which may gradually extend and thus form one large ulcer. A large patch may present three or four ulcers divided by septa of mucous membrane. Very often the terminal six or eight inches of the ileum is one large

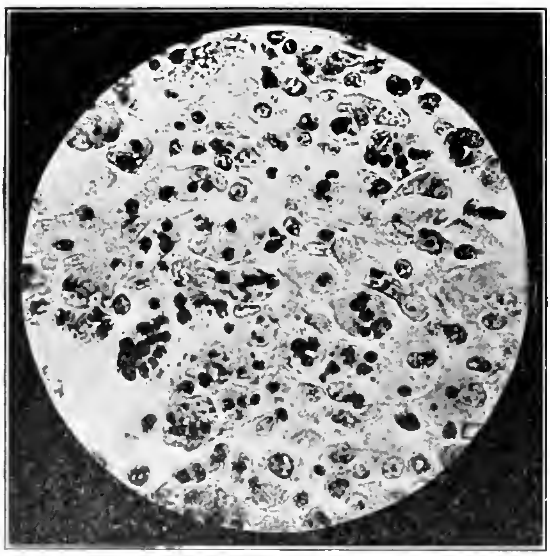

FIG. 4811.—High Power from Fig. 4810 showing Formation of Phagocytic Cells in the Lymph Nodules in a Peyer's Patch. (From Mallory.)

ulcer, with islets of mucosa left here and there. Those originating from the patches naturally affect an oval form with the long diameter in the direction of the gut, and those originating in the solitary glands affect a spherical form. In rare cases the ulceration may extend slightly beyond the confines of the glands. The sloughing or disintegration of the new tissue being completed, there is no induration or thickening of the base or edges of the ulcer. The base of a typhoid ulcer is smooth and clean, and is usually formed of the submucous or muscular coat of the intestine—occasionally of the peritoneum alone. The edges are thin and undermined, and consist of a well-defined fringe of congested mucous membrane, as may be seen by floating the gut in water.

Healing, or *cicatrization*, is the fourth stage. The majority of deaths occur before this stage is reached. The process begins with the development of thin granulation tissue, which covers the base of the ulcer and gives it a soft, shining appearance. The undermined edges approximate to, and unite with, the floor of the ulcer,

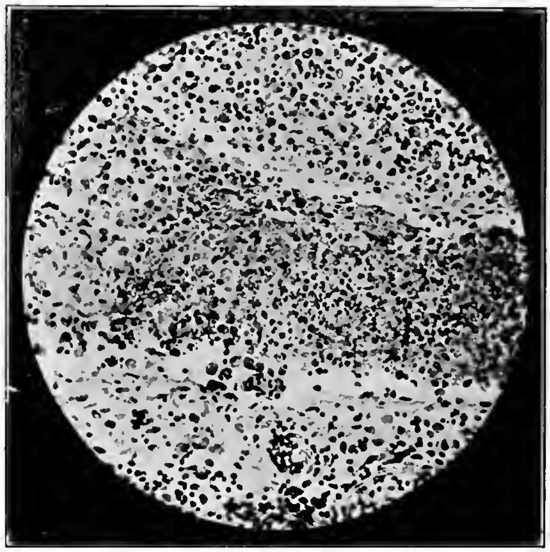

FIG. 4812.—High Power from Fig. 4810 showing Formation of Phagocytic Cells in the Lymph Nodules in a Peyer's Patch. (From Mallory.)

and from its margin new epithelial covering is gradually formed. The gland structure is not regenerated. The site of a healed ulcer is slightly depressed, is less vascular than the surrounding mucous membrane, and is pigmented.

In some cases, especially of relapse, the floor of the ulcer becomes the seat of a secondary ulceration; or occasionally an ulcer heals in one part and extends in another; and again, there may be ulcers healing in one part of the intestine, with fresh ulcers and patches in a state of hyperplasia elsewhere.

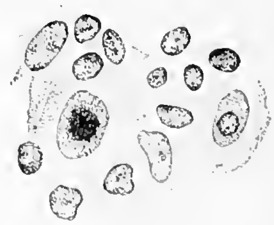

FIG. 4813.—From Periphery of Lymph Nodule, showing a Large Cell of the Reticulum in Mitosis. (After Mallory.)

The secondary ulceration is said to be more apt to cause profuse hemorrhage and perforation than the primary sloughing of the glands.

The Mesenteric Glands.—The changes in these glands are comparable with those in Peyer's patches. The distribution of those affected usually bears a relation to the involved part of the intestine, but is more extensive. The process is also similar and practically synchronous with that in the intestine. These glands likewise are the seat of an acute hyperplasia, which usually undergoes a gradual process of resolution. Softening and suppuration may exceptionally occur, or, the capsule of the gland being destroyed, the softened matters may escape into the peritoneal cavity, causing peritonitis.

Liver and Gall Bladder.—The constant changes (focal necroses) always occurring in the liver in typhoid are of no practical value. Rarely, however, abscess of the liver may occur, and more often a cholecystitis or cholelithiasis may be due to this infection, for which surgical interference may be required. Typhoid bacilli have very often been found in the gall-bladder (Chiari found them in twenty-two out of twenty-four cases), and they are known to persist there for a very long time, seven years in one case. They are supposed frequently to form the nucleus of calculi.

FIG. 4814.—From near the Periphery of Lymph Nodule, showing Newly Formed Cells Beginning to Incorporate the Lymphoid Cells. (From Mallory.)

Spleen.—Changes in the spleen are comparable to those of a Peyer's patch. Except in cases with previous disease of the organ, or in elderly persons, or in cases with much distention, the spleen is generally sufficiently enlarged to be felt. The enlargement is due to hyperæmia and hyperplasia. In the second week it is smooth and tense, dark-red on section. In the third week it is larger, softer, and darker. With defervescence these changes subside and the organ becomes of tough consistence. Infarcts and abscesses very rarely occur. Perisplenitis is rather more common.

Urinary Organs.—The kidneys are almost always enlarged in the second week and hyperæmic on section. Febrile albuminuria is the rule. Following this is parenchymatous degeneration. Infarcts and abscess of the kidney with typhoid bacilli in pure culture have occurred.

Cystitis may occur, but there may be large numbers of bacilli in the urine without causing symptoms; 170,000,000 per cubic centimetre have been estimated by Petruschky, which indicates the importance of disinfection of urine as well as other discharges.

FIG. 4815.—From Centre of Lymph Nodule, showing the Newly Formed Cells Filled with More or Less Digested Lymphoid Cells. Several red blood globules have also been incorporated. (From Mallory.)

TREATMENT.—Treatment properly includes the whole management of the patient. In those not uncommon cases in which the evening temperature does not rise above 102° F., nor the pulse advance beyond 110, and there are no complications, the actual "treatment" may not go beyond rest in bed and a modified diet.

A patient being fairly suspected of typhoid fever should be ordered to bed. The physician should immediately inform himself, when practicable, of the condition of the house drainage and water supply. The origin of the disease should, if possible, be discovered and corrected. The ventilation and regulation of the temperature of the sick room should be secured. Carpets, curtains, window hangings, and unnecessary furniture, it is well to remove. The bed is best in the middle of the room, certainly not in the corner; a second bed or movable couch is very desirable. The mattress should be neither very soft nor very hard—hair is the best material, and upon it a rubber cloth should be placed. The bed covering should be light; fever patients are apt to be too warmly and weightily covered. The patient's pulse and temperature should be taken at least twice a day, say between 6 and 8 A.M. and between 6 and 8 P.M. and recorded on a chart; if they can be taken oftener, so much the more accurate picture is given of the course of the disease. A three-hour chart is always instructive, and sometimes most desirable. The temperature in the axilla is sufficiently accurate for practical purposes in this disease, if proper precautions—such as wiping out the axilla and keeping the arm close to the side—are observed.

During the first week of typhoid fever many patients undoubtedly get out of bed to evacuate the bowels, and it is very seldom that any ill result can be traced to this; it is, however, safer and in the end more convenient to insist upon the use of the bedpan from the first, although to some its use is very uncomfortable, and regard should be had to the form most convenient to the individual. The *dejecta should be persistently and unfailingly disinfected; too much stress cannot be laid upon this point.* They should be passed into a disinfectant solution, another portion of which should be added after their passage, and the whole thoroughly mixed. The same injunction applies to the urine, and in less measure to the sputum. These points will be referred to again under the head of Disinfectants.

FIG. 4816.—Lymphatic Vessels of Mucous Membrane containing Phagocytic, Lymphoid, and Plasma Cells. (From Mallory.)

Soiled bedding, clothing, linen, etc., should be placed in a disinfecting solution before being taken from the sick-room, and when taken thence placed, as soon as possible, in boiling water.

It is desirable, even when there is no hyperpyrexia, that the patient be sponged morning and evening. Water at any desired temperature, with or without the addition of vinegar, alcohol, bay rum, toilet vinegar, etc., may be used. When the fever is pronounced, the water should be cool, about 75° F., and the sponging repeated more frequently. The process is best carried out by placing an old blanket under the patient and going over different portions of the body successively.

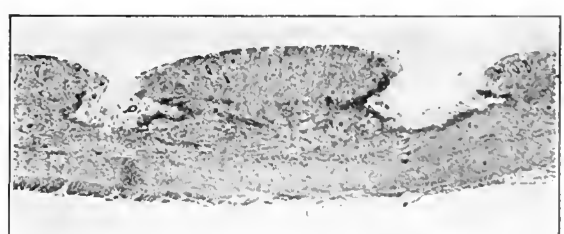

FIG. 4817. Two Ulcers in Large Intestine Following Typhoid Lesions of Solitary Lymph Nodules. (From Mallory.)

DIET.—These details attended to, the regulation of the diet is of prime moment. The general principles to follow are that it be easy of administration; that it be suitable in amount; given at proper intervals; easily digested, unirritating in its passage through the alimentary canal. Good pure milk may be made to meet these requirements better than any other one thing. The individual as well as the disease is to be considered; but, in general, from two to four ounces of milk every two to four hours, or two to four pints in the twenty-four hours, will be indicated during the first three weeks. If too much is given at a time, hard curds are formed in the enfeebled stomach; if too much is given in the twenty-four hours, large and distending masses of pultaceous fæces are formed in the bowel, unless diarrhœa prevents this. The inclination of the patient may often be consulted with advantage; but a certain minimum amount of nourishment is to be insisted on through the early weeks. When milk in small quantities disagrees, lime water, aerated waters, or boiling may be resorted to as diluents. A few patients cannot, or will not take milk in any form. And even for those who can, for whom it is the staple, a variety is needed. Albumen water, prepared by straining the whites of eggs and adding an equal quantity of water, with proper flavoring, is a good

FIG. 4818. Typhoid Swelling and Necrosis of Appendix. (From Mallory.)

FIG. 4819. Two Lymphatics Beneath Peritoneum, Over Appendix; Filled Partly with Phagocytic Cells, Partly with Serum. (From Mallory.)

substitute at times. Broths of beef, of veal, of chicken, or of mutton, given twice a day in addition to milk, four to six ounces each time, or oftener and in somewhat smaller quantities without milk, are useful, and often agreeable. Barley or rice may be boiled in the water, and the whole should be well strained. An egg, if really fresh, may be dropped in and stirred up. Beef juice, if not increasing the activity of the bowels, may be given with advantage; the stimulation thus provided is very useful, and nourishment may be secured in other ways. For increasing the digestibility of milk, broths, beef teas, etc., the peptonizing process may be resorted to. Chocolate boiled in milk or water, if finely ground and not highly flavored, and cacao deprived of fat and treated in the same way will sometimes prove useful and acceptable adjuvants to other diet. The Germans give fruit soups, made by boiling fresh or dried fruits in water, flavoring with sugar, lemon peel, etc., and straining; these are refreshing, but have little nourishment. Wine whey made with sherry or Madeira, milk punch made with brandy or rum, eggnog, Bordeaux if really good, may be given in addition to the above articles if required. There are now to be had a great variety of non-irritating starchy foods or cereals which, properly prepared, may be useful. Koumyss and matzoon should be mentioned. A few of the forms of nourishment most suited to the early weeks of typhoid fever have been suggested, the practical experience of each practitioner will doubtless suggest others. A state of solution, requiring only absorption and not digestion, would be the ideal one for the admin-

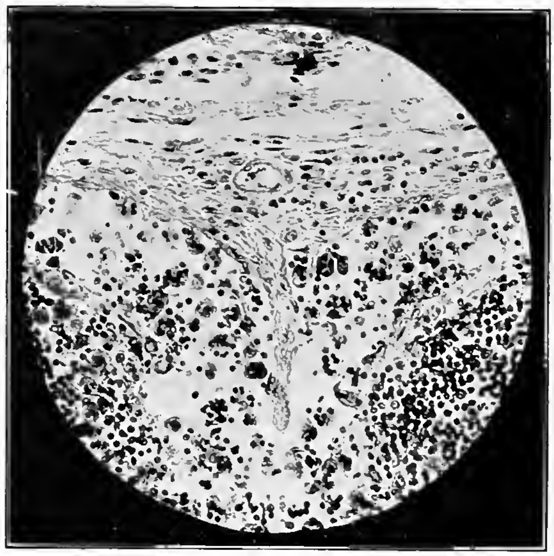

FIG. 4820.—Peripheral Sinus of Mesenteric Lymph Node Distended and Containing many Phagocytic Cells. (From Mallory.)

istration of nourishment in febrile dyspepsia. Pavy and Hoppe-Seyler have shown, however, that the stomachs of animals in a pyretic state may be made to yield a digestive fluid.

Diet in Convalescence.—When the temperature falls to normal, and convalescence begins, the vexed question of increasing the diet arises. Patients do, unknown to their doctors, eat solid food all through an attack of typhoid fever with impunity. Still more often, and this sometimes with the doctor's consent, they begin to eat freely with the return of appetite and the fall of evening temperature to the normal, and this without evil consequences. I think, however, that the old rule—if one must have a rule—to wait a week after the evening temperature remains at normal before increasing a diet as liberal as that outlined above either in amount or consistence, otherwise than very gradually and tentatively, is a good one, and that he who follows it in his practice will, in the long run, have fewer relapses and shorter and better recoveries. Eggs—raw, soft-boiled, or dropped—oyster soup with a finely crumbed cracker, porridges of various consistencies, meat juice, scraped beef, soft dipped toast, etc., may gradually be added or increased in amount, while the digestive and absorptive organs are recovering their normal activity and chemistry. Care should be taken well on into convalescence that the food, of whatever description, be taken in moderate but frequent portions.

A somewhat more generous dietetic treatment than that suggested above is allowed by some practitioners. Dr. F. C. Shattuck finds that his experience at the Massachusetts Hospital, compared with that of his colleagues, favors such a practice. Peabody, of New York, is also an advocate of more solid nourishment.

Drinks.—A fever patient should have a liberal supply of pure cold water. He is not likely to take more than he requires. All the conditions present indicate its necessity. Pieces of cracked ice, kept in a flannel crater over the top of a bowl, and covered with flannel, at the bedside, will be very grateful to the dry mouth if given occasionally. The unmedicinal, not too strongly aerated, waters are at times refreshing. Some practitioners rely a good deal upon the administration of some one of the mineral acids—dilute hydrochloric, sulphuric, or phosphoric. Water acidulated with one of these in the proportion of a drachm to the pint makes an acceptable drink. It is important to keep the mouth as clean and moist as possible, for which purpose the alkaline waters, glycerin and water, or lemon, the same with a little borax added, may be employed.

Bowels.—It is not often that interference with the bowels is required. If the diarrhœa is exaggerated, the stools being both copious and frequent—more than four or five in the twenty-four hours—after the diet has been regulated, it may be thought best to give a suppository of a grain of opium, a rectal injection of laudanum in starch or water, or some bismuth by the mouth. On the other hand, constipation may be present in such degree as to increase the dulness and pain in the head. At such times a rectal enema, or even some castor oil or a Rochelle powder, will do great service. But, as said, if the diet is properly regulated one need seldom interfere with the bowels. Some practitioners, especially among the Germans (Wunderlich, Liebermeister, Friedreich), favor the early administration of calomel—before the ninth day—in doses of eight grains, three or four times daily, for one or two days. They maintain that the subsequent diarrhœa is thereby diminished, the course of the disease is rendered lighter, and not rarely aborted, and the mortality rate diminished. Calomel is given to remove the poison from the bowel, as well as to antagonize it. The early use of calomel, which sometimes is undoubtedly attended with apparently favorable results, is a revival of an earlier practice.

Various antiseptics and eliminatives, separately or combined, have been employed in recent years to antagonize the toxic bacteria and their products in the bowel, or to remove them therefrom. To many of the most careful and experienced clinicians these measures do not commend themselves either theoretically or practically.

When tympanites is troublesome, turpentine stupes or ten drops of the oil in emulsion at intervals internally, guaiacol carbonate, five grains, a simple enema, or the careful introduction of the long rectal tube are all, at times, useful.

Fever.—In the treatment of any febrile disease, and especially of typhoid, it is not to be forgotten that a continuous high temperature is more exhausting than an intermittent or remittent temperature which reaches a higher maximum. Moreover, in estimating the bearing of any temperature the frequency and character of the pulse and the condition of the nervous centres should be carefully considered. An evening temperature of 102° F., or even of 103° F., with a morning remission, may be regarded as the normal result of the typhoid process. An evening temperature rising above 103° F., especially if the morning remission be slight, suggests the propriety of interference. The various modes of controlling temperature may be classed under the two heads of (1) the external application of cold, and (2) the internal exhibition of antipyretics.

1. Cold may be applied externally by means of sponge baths, the wet pack, sprinkling the exposed surface of the body, fan baths, tubbing, rubbing with ice, the ice cap to the head.

Baths.—Since the introduction of baths by Brand of Stettin in 1861, their therapeutic value has become thoroughly appreciated. The effect on the mortality has been very noticeable. Before this treatment was in use, the mortality in typhoid fever in hospitals was given variously as from eleven to sixteen—nineteen per cent. (twelve to fifteen per cent., Osler). The mortality now varies with the locality and in different years, but in general is a little over seven per cent. The manner of giving baths varies with the locality and with the practitioner. In the New York, Philadelphia, and Baltimore hospitals tub baths are largely given, whereas in Boston hospitals sponge or fan baths are given and sometimes wet packs are used. Baths are given every three or four hours if the temperature is 102.5° F. or more, and they usually last about twenty minutes. The tub bath is given by immersing the patient carefully, all but his head, into water at about 70° F. Continual rubbing of limbs and trunk is advisable. Patients may collapse during a bath, and a little stimulation just before or after may prevent chilliness and cyanosis. The sponge bath may be given with water at various temperatures to suit the requirements, and may expose the whole of the body or only part at a time. The fan bath is given by covering the patient with one thickness of gauze wrung out of warm water, and which is then fanned to assist evaporation. The gauze is repeatedly sprinkled with warm water, and the amount of water evaporated shows approximately the heat subtracted from the patient. These baths have been proved by experiment to be practically as effectual as tub baths, and they entail much less disturbance of the patient and are generally more agreeable. The kind of bath used may be governed by the effect on an individual case and modified accordingly.

Whatever bath is used—at whatever temperature, whether higher or lower; however prolonged, whether for a longer or shorter time; however general, whether total or partial—the effect to be sought, and which should be obtained, is a lowering of temperature, an improvement of circulation, a toning up of the nervous system, with accompanying restfulness, and often a diminution of delirium, stupor, and tremor, and consequent better sleep and digestion.

The ice cap to the head is generally grateful to the majority of typhoid-fever patients.

2. The Internal Exhibition of Antipyretics.—Among these remedies may be mentioned quinine, salicylic acid, salicylate of soda, digitalis, alcohol, and the coal tar derivatives. Of these alcohol, digitalis, quinine, and the coal-tar derivatives alone demand consideration.

Alcohol.—The administration of alcohol is to be governed by the pulse rather than by the temperature; but although its stimulant and sustaining properties are most marked, it may still be conveniently spoken of in this connection. The alcoholic treatment of fevers was introduced more than forty years ago by Dr. Todd, since when it has at times been used in an excessive and indiscriminate way, from which there has been a proper reaction, and the present tendency is to regulate the use while avoiding the abuse of alcohol in typhoid and other fevers. Sir William Jenner gives in a few words good guidance on this point. When in doubt as to the wisdom of giving alcohol, do not give it, and when there is a question of a larger or smaller dose, prescribe, as a rule, the smaller. If given, it should be for the purpose of attaining a certain definite object and for the relief of certain symptoms. Its effects should be carefully watched, and the desired results obtained with the smallest possible dose. Its administration, except as a gentle stimulant in the form of wine, of wine whey, or of milk punch, is rarely indicated before the end of the second week. In the presence of a dry brown tongue, of unusual tremor, suggesting deep sloughs of the intestine, of active delirium, or in almost any case with a rising pulse of 120, alcohol should be given, and the dose regulated according to the effects, as shown by pulse, tongue, and countenance. From four to twelve ounces of brandy in divided doses will usually be sufficient in the twenty-four hours, but in advanced cases manifesting much exhaustion, sixteen and even twenty ounces may be required, and will sometimes turn the scale between death and life. The addition of five grains of carbonate of ammonia, every two or three hours, or of a drachm of aromatic spirits of ammonia, is useful and will limit the amount of alcohol required.

Digitalis.—Digitalis was recommended by Murchison in typhoid to control the febrile movement. It is supposed to equalize the circulation by its action on the peripheral terminations of the vaso-motor nerves, to which the arteries of the mesenteric system respond more than the superficial vessels; at the same time the primary effect upon the heart is to slow and steady its action by stimulating the vagus. Too small a dose will not produce the first effect; too large a one will accelerate and then paralyze the weakened heart, and a fall in temperature will follow, as it would the exhibition of any depressing poison.

Quinine.—Many practitioners are in the habit of giving eight grains of quinine during the twenty-four hours as a tonic and stimulant to the heart's action; but to get the antipyretic action, much larger amounts in concentrated doses must usually be given. If the quinine is given in the evening, the fall of temperature coinciding with the usual morning remission will be greater; if it is given in the morning, the evening maximum will be modified. Less than fifteen grains given in a single dose, or within the space of an hour, will usually prove disappointing in lowering appreciably a high temperature; more than thirty grains so given is liable to cause cerebral and gastric disturbances. When quinine is effective, the temperature begins to fall in a few hours, reaches its lowest point in six to ten hours, and remains below the previous maximum for twenty-four hours or longer. In some cases quinine is not well borne, and in not a few it produces an inappreciable antipyretic effect or none at all. Liebermeister advocated the use of quinine, and Nothnagel still does so, regarding it as the least dangerous of all the antipyretic drugs, even when the heart is in an unstable condition.

The Coal-Tar Derivatives.—The number of these is now very considerable, and their action is better understood than formerly. Some are more effective and less depressing than others. If used at all, they should be used sparingly with caution, and as adjuvants to other measures. With regard to these, as with cold baths, the general ends to be gained should be borne in mind and not the mere temporary effect upon the temperature alone.

Antityphoid Inoculation.—Such inoculations have been practised on a considerable scale upon British troops in India and South Africa. The reports of Prof. A. E. Wright, of the Army Medical School at Netley, as to the degree of protection obtained, seem promising, but they lack precision, and the actual value of the process is still to be determined. (See Addendum on p. 951.)

Serum Therapy.—Several different experimenters have prepared typhoid antitoxins by injecting horses with cultures of the typhoid bacillus, and subsequently patients have been injected with these sera. The reports of the results are conflicting and unsatisfactory. The blood serum of patients convalescent from typhoid fever has also been used, with equally indefinite results. This question is still in an undeveloped stage.

COMPLICATIONS AND SEQUELÆ.—Although, for the sake of brevity, I have avoided describing minutely the various pathological changes and clinical complications, other than those connected with the bowels and especially characteristic of the disease, which are incident to typhoid fever, some of these are encountered in so large a number of cases, or are of such importance, that they merit separate mention.

Recrudescence and Relapse.—These are both common phases of typhoid fever, and it is not always easy to classify each return of pyrexia under the one or the other term. In general, a sudden temporary elevation of temperature would be called a recrudescence, and a more gradual and prolonged elevation a relapse. A typical simple relapse, as exhibited on a chart, shows a rising temperature following some days of normal temperature after the primary attack has run its course. According to Irvine, "the temperature begins to rise, and continues to rise, with little intermission, until it reaches its height on the fifth day of relapse; from the fifth day to the eighth or ninth day it is steady, but shows a slight inclination downward; on the eighth or ninth day it falls suddenly several degrees, possibly to subnormal levels; from such levels it ascends even to former heights, but this rise in simple cases is, so to speak, ephemeral. Fever persists to the fifteenth day, when in the simple cases a rapid, though intermittent, fall continues to the twenty-first day of the disease, at which time convalescence commences, and goes on with remarkable rapidity in many cases."

This is a very idealized picture, even of the simple relapse. Relapse indulges in quite as many freaks as the primary typhoid may indulge in. To appreciate this, it is only necessary to remember that the same case may experience several (two, three, or even four) relapses. The relapse may be engrafted immediately upon the primary attack; it may complicate or be complicated by recrudescence; one relapse may be intercurrent with another, etc. Relapse is generally accompanied by a return of the characteristic symptoms, such as diarrhœa, rose spots, enlargement of the spleen, and it is liable to any of the complications attendant upon primary typhoid. But the duration is generally shorter, and, notwithstanding the debilitated state of the patient, a fatal termination is less common than in primary typhoid.

Recrudescence is generally due to some indiscretion; true relapse is probably the result of a secondary auto-infection with the typhoid poison, and will be frequently observed where there has been no imprudence whatever, either of diet or otherwise. On the other hand, instances of various indiscretions unattended by any evil consequences, and of an early return to solid food against orders without paying the threatened penalty, are almost equally common.

Perforation.—Perforation is the most fatal complication of typhoid fever. It occurs in from one to two per cent. of all cases, and is responsible for about ten per cent. of the deaths. It occurs most often in the third week, but may be as early as the fourth day, or as late as in the fourth month during a relapse. There have been more cases in men than in women. The perforation occurs in the last two feet of the ileum in over eighty per cent. of the cases. In very many it is in the last foot. Perforation may not always be fatal. It may occur between two coils of intestine which are adherent, or probably more often it is immediately walled off by fibrin and may heal. It is unwarrantable, however, to expect a perforation to heal under medical treatment, and as soon as the diagnosis is made, surgery offers the real hope of recovery. It is of the utmost importance to make the diagnosis early, but the subject presents great difficulty.

There are causes of peritonitis other than perforation, and these may be of mild grade and recover without surgical interference. There is no pathognomonic sign of perforation in typhoid fever. The most characteristic symptom is sudden, severe, abdominal pain, persisting and increasing for some time, accompanied perhaps by collapse, a fall of temperature, a rise of pulse, nausea and vomiting, with sometimes abdominal spasm which persists, and sometimes hemorrhage. It was hoped at one time that the leucocyte count would be useful, but though in some cases it was found to rise rapidly after perforation, in others there was a diminished leucocytosis. On the other hand, there might be a leucocytosis of

28,000-70,000 in obstruction without perforation. There is then no sure diagnostic sign of perforation, but the diagnosis must be made from the group of symptoms present in a given case. However, as the benefit to be derived from operation is offered only when the diagnosis is made early, the physician should secure a consultation just as soon as the condition is suspected. Some authorities advise a small abdominal incision under cocaine to allow taking a culture from the peritoneal cavity, and to finish the operation if pus is found, but it is hardly reasonable to suppose that such a procedure would do no harm to a patient who is already very sick with an acute disease.

Hemorrhage.—Hemorrhage is a more frequent complication than perforation, but fortunately is not so fatal. It occurs in from four to six per cent. of all cases, and is probably responsible for death in about fifteen per cent. of cases. The exciting cause of hemorrhage may be an error in diet, or restlessness or distention, but it may occur in spite of the utmost care. It is most frequent in the second and third weeks, but like perforation it may be the first noticed symptom in an ambulatory case, or it may occur in the eighth week during a relapse. It is less common in children, and according to statistics less serious in women. Pain may accompany or precede hemorrhage, and sometimes hemorrhage occurs with perforation, obscuring the diagnosis. The amount of blood lost may be an inconsiderable streaking of the fæcal discharges due probably to an intense hyperæmia of the lymphoid tissue of the intestine, or it may be very copious—more than a quart—and clotted, and is then probably due to the erosion of a larger vessel.

The effect of the hemorrhage depends on the amount of blood lost. Some authorities maintain that a moderate loss of blood in a robust patient with high fever may even be beneficial. Certainly sometimes the effect of hemorrhage is inappreciable. In more severe cases there are the signs of acute anæmia, pallor, coldness, small, feeble, more rapid pulse, and there may be a marked drop in temperature. Sometimes these signs are present before the blood has appeared. The patient may even have fatal collapse and die within a few hours, before the blood appears in the stools. More commonly the hemorrhages are repeated at intervals and the patient may succumb within a few days. The treatment of hemorrhage depends on the effect. Styptics cannot be expected to check it. Opium may produce quiet, depress the heart's action, and reduce peristalsis. The diet should be restricted for a time and the baths withheld temporarily. Stimulation is not usually given, but if the patient's condition requires it, subcutaneous stimulation may be of some benefit, and subpectoral infusion of salt solution, though irrational, may possibly tide the patient over a severe acute anæmia. The local application of cold externally is resorted to, but is not to be recommended.

Epistaxis.—Nose-bleed, in the period of invasion, is so common an occurrence as to be considered almost a diagnostic detail. At this period it is usually slight, requires no treatment, and is even a source of relief to the headache and dulness. Later in the disease nose-bleed is less usual, but is apt to be more profuse, and may necessitate plugging of the posterior nares. Exceptionally life may be endangered, and an enfeebled patient may not rally from a severe epistaxis in the later stages.

Bronchitis occurs undoubtedly more often in cases in which early and suitable care has not been given to the patient, but is quite common in other cases as well. It is often due to weakness and the dryness of the buccal and pharyngeal mucous membranes, and to the consequent inability to raise and expel the bronchial secretions. The râles may be so loud as to be audible at a distance from the chest. Bronchitis is sometimes associated with a lobular pneumonia, and in the later stages with hypostatic congestion of the lungs. All these conditions disappear with the pyrexia, and their best treatment is that directed to supporting the strength of the patient and controlling the toxins.

A genuine croupous pneumonia sometimes complicates the disease; and, when appearing early, may be regarded as a direct manifestation of the typhoid poison, to which the term typhoid-pneumonia is applied.

Thrombosis.—Venous thrombosis is frequent both as a complication and as a sequel. It occurs generally in cases which have run a prolonged and exhausting course. The femoral veins and their branches are those most often affected, and of these the left more frequently than the right. An elevation of temperature, a hardness of the vein, and swelling of the leg announce and accompany the condition. Complete rest, elevation of the leg, flannel bandaging, and, later, possibly some small blisters, are indicated as treatment.

Either as a complication or as a sequel, thrombosis is sometimes painful and tedious, but fortunately only in exceptional instances does it give rise to embolism of the pulmonary artery and death.

Acute Otitis Media.—This is a by no means infrequent complication, developing usually from the second to the fourth week, and occurring in from two to three per cent. of the cases. It is generally of infectious origin by way of the Eustachian tube, and is associated with the patient's prostration and altered and accumulating buccal and pharyngeal secretions. It often complicates the temperature chart and leucocyte count, and may require special treatment.

Typhoid Psychoses.—Various psychoses may accompany or follow typhoid fever. Of all the acute diseases it is the one most often accompanied by mental symptoms. In all such cases the family history should be inquired into, especially with reference to the prognosis.

Kraepelin groups the conditions which present themselves as follows: (1) Initial delirium; (2) febrile psychoses; (3) asthenic psychoses.

Initial delirium is said to be the rarest form, to exhibit the most rapid course, and to offer the worst prognosis, over fifty per cent. ending fatally. Unsound heredity is a predisposing cause.

Febrile psychoses embrace the great majority of mental cases developing in typhoid fever, and offer a relatively good prognosis.

Asthenic psychoses are associated with the period of convalescence, and are apt to present long, weary courses and a doubtful outlook.

Neuritis.—Various forms of neuritis, local and general, accompany and follow typhoid fever. Among others, "tender toes" is mentioned by Osler, making the weight of the bed covering insupportable. The "typhoid spine" is a sequel to which Gibney called attention, and which he regarded as a perispondylitis, but which others consider to be dependent rather upon a general neurasthenic condition.

Necrosis and Periostitis.—When these occur it is usually as sequels, and such cases should be referred to the surgeon.

Disinfection.—In discussing the etiology and the pathology of typhoid fever, the occurrence of typhoid bacilli in the body and their resistance and tenacity of existence under different conditions were considered. Careful thought with regard to these matters indicates what a grave responsibility rests upon those associated with typhoid-fever patients, and what great care should be used in disposing of all exereta and in guarding in other ways against the dissemination of the germs of the disease.

In private practice, where possible, a room should be chosen which will combine good ventilation and sunshine with partial isolation and easy means of disposing of exereta and soiled linen without contaminating any more of the house than is necessary. Just as soon as the diagnosis is suspected, rigid rules should be made and enforced regarding the disposal of exereta and the disinfection of all articles which come in contact with the patient. Of course, different circumstances will require varied arrangements, but if the principles are understood and the objects to be attained are considered, the manner of their achievement is indifferent. In the city, where injury to plumbing is to be avoided, formalin and carbolic acid are the best disinfectants. Formalin is easy to use, efficacious, not very expensive, and the odor is not lasting. Fæcal discharges should be received into a vessel containing about a pint of dilute formalin (ten per cent.). After defecation the stools should be covered with the solution, then mixed thoroughly, best with a stick that can be burned, and after standing for some time they may with safety be emptied. Urine should always be disinfected. This may be done with corrosive sublimate, five per cent. carbolic acid, or chlorinated lime, but best by adding one-fortieth of its volume of formalin.

To disinfect urine in the bladder of patients *urotropin* is given in doses of from eight to ten grains three times a day for two days each week until convalescence is completed. Soiled bed linen and other articles which may be infected should be soaked in disinfectant (five per cent. carbolic-acid solution), and then when possible boiled, or exposed to dry heat in a disinfecting chamber. The sputum should be disinfected and may usually be burned. The nurses and attendants, after coming in touch with the patient, should also disinfect their hands carefully, both for their own protection and for the protection of others. The disinfection of thermometers and other utensils should not be overlooked.

In the country disinfection is exceedingly important. Any patient may be the source of a serious epidemic. Here the stools may be disinfected by mixing with an equal quantity or more of "milk of lime," which is slaked lime with four volumes of water, and after standing for two hours, they may be put in the privy vault or burned. Milk of lime should also be thrown liberally into the privy. The urine may be disinfected by chlorinated lime (1 to 32) or corrosive sublimate. The sputum should be burned, and linen, etc., all carefully disinfected. If any of those attending the sick also do farm or dairy work, especial care and diligence should be observed in preventing them from spreading the disease.

Convalescence.—Convalescence from typhoid fever is always slow, and may be very prolonged. It is always a matter of weeks, and may be a matter of many months. During this period a general supervision of the patient is desirable—care as to food, clothing, exercise, occupation, rest.

Notwithstanding the changes in our views incident to the development of bacteriology and minute histology, a better summing up of the disease process in its relation to the process of convalesence cannot be given than in the closing words of Hoffmann's volume on the pathological-anatomical changes in the organs in typhoid fever: The poisonous materials are, as a rule, taken into the body with the food, and carried into the blood from the lower portion of the ileum, as the place where the food tarries the longest, and where particularly favorable conditions for absorption are found. With this absorption, tissue changes take place in these parts which cause the onset of a severe febrile movement, and this in turn entails a parenchymatous degeneration of the various organs. Under an extreme development of these phenomena, attended by a number of unfavorable complications, the patient succumbs. But in most cases the fever declines with the return of the intestine toward health. Nutrition regulates itself, and the degenerated organs are gradually renovated.

When one therefore reflects how in all parts of the body large portions of important organs are destroyed during the typhoid process, one easily understands why typhoid patients in general experience such pronounced weakness for such a long time, and why typhoid fever is followed by so much longer convalescence than so many other less generally destructive diseases. The restoration of such a large portion of the most important portions of the system as are destroyed during the disease taxes to the utmost the ability of those which are left, and is rendered laborious precisely by the fact that the very delivery of new material for rebuilding is greatly impeded by the destruction of large areas of the lymph glands in the intestine.

Reflecting on these points, instead of being surprised at the slowness of convalescence, one is led to wonder at the recreative force which, undaunted by such impediments, builds up afresh in a comparatively short period a large part of the whole body; and, at the same time, one understands why it is that the convalescent, after passing safely through an attack of typhoid fever, feels rejuvenated and as if he were born anew.

TYPHOID FEVER: BACTERIOLOGY. See The Appendix.

TYPHO-MALARIAL FEVER.—This term, which was suggested by Woodward in 1862, and has since been widely adopted, cannot be justified upon scientific grounds; for, as conceded by Woodward himself,[1] and generally admitted by recent authorities, "it does not designate a distinct type of disease, but is simply a term which is conveniently applied to the compound forms of fever which result from the combined influence of the causes of malarious fevers and of typhoid fever."

If we accept this definition of the term upon the authority of its author, we shall be obliged to admit that typho-malarial fever is simply a clinical variety of typhoid fever in which the symptoms are more or less modified by the fact that the patient has also been subjected to the influence of the malarial poison, and the propriety of making a separate heading for such cases in our nosological tables may be questioned.

If, in accordance with this definition, the sole difference between typhoid fever and typho-malarial fever consists in the presence or absence of a malarial complication, it would be reasonable to expect that the mortality from the complicated cases—typho-malarial—would *at least* equal that from the uncomplicated cases. But if we refer to the statistical tables published in the first medical volume of "The Medical and Surgical History of the War of the Rebellion," we shall find that this is not true of the cases included under this heading by the medical officers of our armies during the war. On the contrary, *the mortality from typho-malarial fever is very much less than from typhoid fever.* This is shown by the accompanying table, taken from the writer's work (1884) on "Malaria and Malarial Diseases," page 83.

We find by referring to the third column in this table that the percentage of mortality in the cases designated simply "typhoid" was, in the case of the white troops, more than five times as great, and in the case of the colored troops more than three times as great, as in the class of cases designated "typho-malarial." It will scarcely be maintained that a complication can exercise a favorable influence upon the severity and fatality of a specific disease. We are, therefore, obliged to suppose

ANNUAL RATE PER 100 OF SICKNESS AND MORTALITY FROM CONTINUED AND MALARIAL FEVERS IN THE ARMIES OF THE UNITED STATES DURING THE CIVIL WAR.

	Ratio of Cases to Mean Strength.		Ratio of Deaths to Mean Strength.		Ratio of Deaths to Cases.	
	White.	Colored.	White.	Colored.	White.	Colored.
Typhoid	2.62	2.14	1.05	1.19	39.89	53.24
Typho-malarial..	2.43	3.94	.19	1.01	7.08	17.28
Remittent	11 62	16.05	.16	.52	1.39	3 27
Intermittent	36.54	62.77	.04	.06	.18	.10
Congestive intermittent........	.53	1.32	.14	.36	26 23	31.30

either that this malarial complication only manifests itself in the milder forms of typhoid; or that a large share of the cases diagnosed "typho-malarial" are simply uncomplicated typhoid of a mild form; or that under this heading a large number of cases are included which are not typhoid at all, but belong to a distinct species of fever of much milder type. In the latter case, it is evident that it will be necessary for those who maintain the existence of a distinct form of continued fever to define its characters, and to give it a specific name, inasmuch as typho-

The disease runs its course in two or three weeks, sometimes even in less time, and then subsides spontaneously, leaving no unpleasant effects. *Such cases are often mistaken for miasmatic remittent*, especially as they not infrequently have a daily remission and exacerbation of the febrile symptoms."

Since the introduction of the term "typho-malarial fever," such cases are very commonly classed under this heading, and it is certainly a decided gain to have them rescued from the group of malarial fevers to which they were formerly so often relegated, under the convenient heading "remittent fever," a term which in this country, in Europe, and especially in India, has been made to serve as a catch-all for a variety of febrile complaints differing widely in their etiology and having nothing in common except a more or less remittent character of the pyretic movement.

The supposition that a large share, at least, of the cases which appear in our statistical tables under the heading "typho-malarial fever" are identical as regards etiology with the cases included under the heading "typhoid fever" is supported by a consideration of the data contained in the first medical volume of "The Medical and Surgical History of the War of the Rebellion."

This is shown by the following table, and remarks taken from the writer's work on "Malaria and Malarial Diseases," heretofore referred to (page 21):

WHITE TROOPS IN FIELD, GARRISON, AND HOSPITAL—GENERAL SUMMARY.

malarial fever is now generally recognized as being simply a clinical variety of typhoid.

There can be no doubt that a large proportion of the cases which in our army statistical tables appear under the heading "typho-malarial fever" are in truth mild cases of typhoid. And it may be that under the influence of a malarial complication the pyrexia in such cases has a more decidedly remittent character than in similar cases without complication. But it must be remembered that uncomplicated typhoid often presents a decidedly remittent character at the outset of the attack, and that in infants the pyrexia of enteric fever commonly presents this character in so marked a manner as to have led to the designation "infantile remittent." There is reason to believe that the non-recognition of this fact leads to frequent mistakes in diagnosis, and that many cases of simple enteric fever, and especially the mild cases, are improperly classified under the headings "malarial," "typho malarial," and "remittent fever." This results largely from the fact that the diagnosis has been made at an early period in the progress of the disease, before the distinctive characters of typhoid fever have been developed, and at a time when the pyrexia is, as stated, very often remittent in its character. In speaking of mild cases of enteric fever, Dr. George B. Wood, in his "Practice of Medicine" (ninth edition), says: "In some instances the disease presents no other symptoms than those of moderate fever, with the characteristic phenomena of a slight diarrhœa or tendency toward it, some meteorism of the abdomen, and perhaps a few rose-colored spots. The tongue remains soft, moist, and whitish throughout; there is no vomiting, no considerable nervous disorder, no great prostration; in fine, none of these peculiar symptoms commonly denominated typhus.

"The figures in the tables from which our general summary has been made relate to the fiscal year, which includes the period from June 30th of one year to July 1st of the following year; the data, therefore, under the heading 1862, for example, relate to the last six months of 1861 and the first six months of 1862. The change in nomenclature, made in accordance with the recommendation of a board of medical officers, of which Dr. Woodward was a member, took effect soon after the commencement of the fiscal year 1863, and it is quite apparent from an inspection of the table that the class of fevers previously known as 'common continued fevers' subsequently fell into the group denominated typho-malarial.

"The broad fact which our table shows, is that the relative proportion of cases of typhoid fever diminished, and the relative number of cases of malarial fever increased, as the war progressed. Thus, upon comparing the first two years with the last two years, we find that the sum of the annual ratios is as follows: Typhoid fever, first two years, 12.47; last two years, 2 99; malarial fevers, first two years, 81.90; last two years, 103 22. This affords us a criterion for determining whether the group of fevers called, prior to 1863, 'common continued fever,' and subsequently 'typho-malarial fever,' is more nearly allied, etiologically, with true typhoid or with the malarial fevers Taking, as above, the sum of the ratios for the first and last two years of the war, we obtain the following: Typho-malarial fever, first two years, 7 59, last two years, 3.76 Evidently the causes which produced this group of fevers diminished as the war progressed, as did those which produced the fevers recognized as typhoid, while the relative proportion of cases of malarial fevers increased.

"The etiological deduction is apparent, and the reasons for this increase of one class of fevers and decrease of another are not difficult of comprehension. In the first place, our armies moved southward as the war progressed, and came more within the influence of the malarial poison. And, perhaps, this general movement southward, in which, however, the Army of the Potomac did not to any considerable extent participate, carried our troops, to some extent, outside of the endemic prevalence of enteric fevers. This, however, is open to question. In the second place, it is a generally recognized fact that exposure to malaria, and attacks of malarial fevers, not only do not confer immunity, but predispose to further attacks. The increased number of cases of malarial fevers is, therefore, accounted for.

"On the other hand, attacks, however mild, of the specific fevers protect those attacked, to a greater or less extent, from future attacks. That this immunity applies to typhoid, as well as to yellow fever and the eruptive fevers, there can be no doubt. . . .

"The history of armies in all parts of the world shows that new levies are especially subject to typhoid fever, and to the mild continued fever so often called by some other name, while seasoned troops are, to a great extent, exempt from it" (*op. cit.*, page 22).

In further support of the view that the etiological conditions which produce the cases denominated typhomalarial correspond with those which produce typical cases of enteric fever, we may call attention to the fact that the so-called typho-malarial fever frequently occurs in localities where intermittents and remittents are unknown; that it may prevail during the winter months, and in cities which are far removed from malarial influences, that its prevalence is often traced to insanitary conditions of the same nature as those which are concerned—as predisposing causes, at least—in the production of epidemics of typhoid; and, finally, to the fact that in fatal cases, which have been diagnosed as typhomalarial at the outset of the attack, the lesions of enteric fever are commonly found at the autopsy.

If, as some claim, there is a form of continued fever widely prevalent in the United States, which, although influenced by the same predisposing causes, is specifically distinct from true enteric fever, and also from the malarial fevers, properly so-called, then we must protest against the use of the name typho-malarial fever as applied to such cases, inasmuch as, in accordance with the definition given, by the originator of the name, this term is generally understood to designate a clinical variety of typhoid fever. *George M. Sternberg.*

[1] Transactions of the International Medical Congress held in Philadelphia in 1876, article Typho-Malarial Fever.

TYPHUS FEVER.—Synonyms: German, *Fleck-typhus, Fleck-fieber, typhus exanthematicus;* French, *typhus exanthematique;* Italian, *Dermo-tifo, typho esantematico;* Spanish, *Tifus El "Tabardillo,"* or *tifo tabardillo;* Dutch, *Vlekkoorts Kwaadardigekoorts;* Swedish, *Fläcktyfus;* Norwegian or Danish, *Nerve feber, Exanthematisk typhus.* The disease has also been known by various other names as Spotted fever, Camp, Jail, Ship and Hospital fever, Typhus Contagiosus, Typhus Petechialis, Febris Puerpera Epidemica, Morbus Pulicaris, Febris Peticularis, Catarrhal Typhus, Ochlotic Fever, Adynamic or Ataxic fever, Cerebral Typhus, Putrid or Malignant Fever, Irish Ague, Febris Hungarica.

Definition.—Typhus fever is an acute, infectious disease of unknown origin, highly contagious, so far as we know spread only by actual contact, and maintained by overcrowded conditions of population. It occurs in epidemics but may become endemic. It is characterized clinically by severe onset, early and pronounced nervous manifestations, such as prostration and tendency to mental derangement, a rapidly developing macular eruption, which is at first hyperemic but later becomes hemorrhagic, and a fever which terminates by crisis. It presents no specific anatomical lesions, and is in no way related to typhoid fever. It belongs, in all probability, to the group of diseases known as the acute exanthemata.

History.—Typhus fever, since the conditions which favor its development have always been present in the world, has probably followed upon great wars and famines since the beginning of civilization, and fevers are described by ancient writers which are thought to be typhus. In 1083 Carradi [1] and in 1463 Jacobus de Partibus [2] describe epidemics which many writers believe are the first unmistakable reports of the disease; but the great bulk of evidence points to the epidemics recorded by Fracastorius,[3] a Veronese physician, as the first which we can with a degree of certainty pronounce typhus fever. Fracastorius in 1546 published his work entitled "Contagionibus et Morbis Contagiosis," in which he describes an epidemic in Italy in 1505 and 1508, and a second epidemic which he witnessed twenty years later under the name of morbus lenticularis. This disease, though new in Italy, appears to have been well known by the physicians of Cyprus, where the disease was probably epidemic, and whence it may have come to Verona. The second epidemic in Italy, from 1524 to about 1530, spread to France and Spain, over the whole of the German Empire and even to Sweden, returning to Italy toward the end of the century.

Epidemics of typhus fever with dysentery and scurvy recurred in the seventeenth century among the train of evils entailed upon the unhappy empire by the Thirty Years' War. The disease continued to break out both in England and upon the continent during this and the succeeding century. In the eighteenth century it was endemic on the continent and became epidemic wherever want pressed more sorely than usual. In England the so-called Black Assizes became centres of contagion, when at judicial sessions prisoners communicated the disease to judges on the bench and to others in proximity. The cause of the disease was pointed out in 1735 by Browne Langrish [4] to be overcrowding and want of ventilation, so that "people are made to live in their own steams." The disease had been known by various names, chiefly as spotted fever. The name typhus was applied to it about this time (in 1760) by Sauvages.[5] The term is from the Greek, τῦφος, a smoke or fog, which was used by Hippocrates to designate a condition of stupor, and well describes the characteristic intellectual sluggishness of the sufferer from this form of fever. The extensive epidemics of the so-called "Faulfieber" in Austria (Vienna, 1757 and 1759) and Germany (1771 and 1772) were very probably typhus.

The early years of the nineteenth century saw a general epidemic of typhus on the continent. The armies of the French Republic and the First Empire carried the contagion everywhere. Napoleon lost more men by this pestilence than by the armies of the allies. When the tide of war receded the larger towns were left as centres from which epidemics spread from time to time. Great devastation was wrought by typhus among the armies of the Crimean War (1854–56), and in the war between Russia and Turkey in 1877–78 the pestilence visited the Russian camp, prostrating one hundred thousand men, half of whom died. The United Kingdom meanwhile has suffered much. Ireland has been a focus from which, during the last century, five epidemics have radiated. The most severe of these was in 1846. The mortality was very high and the disease spread to England, where it reached its height in the almost incredible number of one million cases (Murchison), and thence to the continent. In the century just closed the epidemics have shown a tendency to confine themselves to the vicinity of the place of origin, a result no doubt traceable to improved sanitation. The ravages of the disease among the Russian forces in the Crimean and Turkish wars were due directly to the horrible sanitary condition of the camps. In the Crimean War the English, whose camp was better managed, suffered less from the pestilence.

In the New World the disease is pandemic in Mexico, where it has existed since the advent of the Spaniards; if it was not known before the conquest under the name of "cocolistle." It is thought by some that the disease in Mexico has been confused with malaria and typhoid fever, and that typhus is exceedingly rare. In the United States there have been several local epidemics during the last century. The first was in New England in 1807. The disease broke out in Philadelphia in 1812, and lurked in the city "in lanes and alleys" until 1821 when Wood, then a student of medicine, studied and reported the disease. Philadelphia suffered another visitation in 1836, the history of which was written by Gerhard[9] who was the first, in this country at least, to establish the difference between typhus and typhoid. Since that time epidemics have visited sundry American cities and have been described by Flint, Da Costa, and Loomis. Typhus was not epidemic on either side during the Civil War. It is true that seventeen hundred and twenty three cases were reported to Washington, but these, as Hutchinson maintains, were typhoid accompanied by conditions which misled the army surgeons in diagnosis.

Few and mild have been the epidemics during the latter part of the century just closed. As Osler has remarked: "The gradual disappearance of typhus fever is one of the great triumphs of modern medicine."

ETIOLOGY.—*Geographic Distribution.*—If the history of typhus fever is reviewed, it will be found that no country of Europe has been exempt from the disease. England and Ireland, Italy and Russia are known as the classic homes of typhus fever, places in which the disease lurks, and from time to time epidemics, whose origin is traceable to these places, occur in neighboring and distant countries, whither they have been brought by means of merchant ships. Immunity from typhus has been claimed for France, but this claim, according to Hirsch, is not warranted, as recorded cases will show. The disease is not unknown in Iceland. In Africa and in Asia, outside India, the disease is, according to Murchison, unknown, but here again Hirsch found trustworthy evidence of occasional cases of the malady in Asia Minor, Syria, Persia, Egypt, Nubia, Tunis, and Algeria. New Zealand and Australia, the Mississippi valley, and the Pacific maritime states have remained free. In Mexico and Central and South America again Hirsch affirms, while Murchison denies, the existence of typhus.

MODES OF CONVEYANCE.—*Contagium.*—The contagium develops and reproduces itself in the body of the typhus-fever patient. The manner in which it is given off from the body is as yet only a matter of speculation. It is thought that the contagium exists in the secretions and excretions of the body and in the exhalations from the lungs and skin. There can be no question on the other hand that the disease is transmitted by so-called common carriers or fomites. The contagium clings to particles of dust, articles of clothing, furniture, and conveyances of various kinds, and retains its pathogenic properties for months. The literature abounds in instances where the disease has been conveyed to hitherto uninfected localities in articles of clothing, etc. The contagium has been carried by dead bodies.

Typhus fever may be transmitted through the air, but not for great distances. It has been demonstrated that in well-ventilated and uncrowded wards, where three or four typhus-fever cases are being cared for, the other patients remain uninfected, while those who have the immediate care of the cases are very frequently affected. On the other hand, in crowded wards or buildings with poor ventilation all are affected who are exposed.

That the disease is of a specific nature and does not occur spontaneously is shown by the fact that articles of clothing containing the contagium cannot infect after they have been subjected to a temperature of 100° to 120° C.

The contagium may be transmitted at all stages of the disease, including the stage of incubation. The period of greatest danger is during the beginning and at the acme of the febrile stage. Upon this point most writers are now agreed, while many of the older writers maintain that the contagium is more often transmitted during the stage of convalescence.

Bacteriology.—We still remain in the dark as to the true nature of the contagium. Whether it is a bacterium or a parasite of some other order is a question yet to be solved. In this disease as in the acute exanthemata many researches have been made, the purpose of which has been to demonstrate the specific cause, but little if anything has been accomplished. It will be unnecessary to more than mention the work of those whose efforts thus far have apparently no other than an historic value.

As early as 1868 E. Hallier, of Jena, described an organism which he called typhus fungus (rhizoporus), and fifteen years later, in 1883, Mott[7] reported the finding of motile spirilla in the blood of a typhus fever patient. Little importance, however, was attached to these reports at that time or since. In 1888 Moreau and Cochez[8] isolated, from the blood and urine of typhus-fever patients, bacilli which they describe as resembling the bacillus typhosus. A year later, in 1899, Hlava, of Prague, made observations on forty-five typhus-fever cadavers. In twenty of these and also in one living subject he found a streptobacillus in the blood, but was unable to demonstrate its presence in any of the organs. Cornil and Babes were unable to confirm Hlava's conclusions. In 1892 Lewaschew[10] described coccus-like bodies in the spleen blood which, when stained, were seen to possess long cilia. He also observed free flagella, to which he gave the name spirochaëte exanthematicum, and these, he thought, represented a different stage in the life history of the organism. He succeeded in growing the organism on ascitic fluid. In the same year Thoinot and Calmette[11] described a flagellate and ameboid organism in the spleen blood of five living patients and from the pulmonary blood of one after death. In 1893 Cheesman[12] described his bacillus sanguinis exanthematicus. In 1894 Dubief and Brühl[13] described their capsulated diplococcus exanthematicus which they found much more commonly in the air passages and sputum than in the blood. When planted on agar a luxuriant orange-yellow growth was obtained. Animal inoculations, in their opinion, were successful in producing a condition which resembled typhus fever. Porter[15] in 1899 isolated a diplococcus in eighty-eight per cent. of one hundred and forty-three cases of typhus, but was also able to demonstrate the same organism in typhoid patients. Obermeyer[14] has reported the finding of a spirillum in the blood, but in his case as well as in similar cases reported by others it is highly probable that relapsing fever was associated with typhus. A field as yet unexplored, and which may prove a source of knowledge, is a systematic bacteriological examination of the eruption itself.

The Influence of Age.—No definite periods of life can be absolutely settled upon at which typhus fever is especially liable to occur. Many statistics have been gathered, and if we were to base our conclusions upon them we should say that in adult life, between the ages of twenty and forty, the disease is most common. However, all things being equal, social and physical conditions, occupation, environment, etc., the first statement must be accepted as the correct one. The disease occurs at the extremes of life. Wiess[16] (1862) *reported a case in which a fœtus of five to six months* showed irregular black petechiæ with vesicles the size of a pea scattered over the body. The spleen was enlarged, and measured 1.5 by 3 cm. Peyer's patches and the mesenteric glands were swollen. The epidemic from which the mother suffered was true typhus exanthematicus, and in this form of typhus the tendency toward abortion is slight. So far as I am able to ascertain, this is the only case of typhus in the fœtus reported. Buchanan[17] reports a case of typhus in an *infant two weeks old.* Older children, however, are more frequently affected than younger ones. The disease is not uncommon in the aged, in which respect typhus differs from typhoid. Buchanan reports a case in a man of eighty.

Influence of Sex.—It has been demonstrated that if males and females are equally exposed to infection they are equally affected. Men are more frequently affected because they are more frequently exposed. Sex therefore plays a subordinate part in the etiology of the disease.

Influence of Race.—No significance appears to be attached by the majority of authors to race influence. But in the Philadelphia epidemic of 1836 "negroes and mulattos suffered from it more severely than others."

Influence of Occupation and Social Conditions.—Only in so far as occupation and social conditions may bring the individual into actual contact with the disease, as in the case of physicians and nurses, can they be regarded of any etiological importance; that is to say, no particular trade either predisposes to or protects against infection. The contrary view, however, is held by many English physicians, who maintain that butchers and workers in fats, such as candle-makers, are relatively immune. Curschmann,[18] however, does not incline to this opinion, as he has seen as many cases in butchers as in other workmen.

Influence of Season and Meteorological Conditions.—The disease is rare in tropical climates, and flourishes chiefly in colder countries, during the winter and spring months, where imperfect ventilation and crowding of population among the poorer classes supply the conditions favorable to its development. Some large epidemics have occurred, however, during the warmer months, notably the one described by Gerhard. Very low altitudes and damp places, as seaport towns, are thought by Hirsch to be important predisposing factors.

Individual Predisposition.—It is generally conceded that influences that tend to lower the bodily tone of an individual, such as illness, poverty, and worry, are powerful predisposing factors. In this respect a striking contrast is offered to typhoid fever which so commonly attacks young, robust individuals. Even among the classes in better circumstances, where hygienic conditions are more perfect, if any be affected it is almost invariably one whose physical strength is at a low ebb. Convalescents from long-continued or acute diseases are unquestionably predisposed to the disease. It was thought by Hildebrand and his followers that tuberculosis gave a relative immunity to typhus-fever patients. Murchison and Curschmann, on the other hand, do not incline to this opinion, as they not uncommonly found the two diseases together. Littlejohn and Ker[19] in their description of the Edinburgh epidemic (1899) inform us that most of the fatal cases occurred in large, muscular men. They are of the opinion—contrary to the observation of others—that a good physique is a disadvantage in typhus.

Immunity.—Typhus fever resembles the acute exanthematous diseases, in that one attack usually protects for many years and often for life. Murchison was attacked twice, and there are other instances of second attacks that might be mentioned. The disease does not, however, recur with the same frequency as does measles. Hildebrand believed that a certain immunity was obtained by physicians and nurses and those who, by constant attendance upon the disease, became accustomed to the poison. Loomis, who in all his well-known experience in typhus fever never contracted the disease, thought that his immunity was due to some personal idiosyncrasy.

Morbid Anatomy.—There are no characteristic post-mortem changes in typhus fever. The external findings are those which accompany all of the acute exanthematous diseases. Traces of the rash are seldom present. The organic changes that occur are those resulting from the pyrexia. Certain phenomena, nevertheless, occur with such frequency as to demand attention. The most important of these are the following:

Changes in the Respiratory Organs.—To a certain extent in almost all cases the respiratory tract is affected. Tracheal and bronchial catarrh and hypostatic congestion are among the more constant conditions met with, and cases presenting these characters have been designated by Rokitansky bronchotyphus and pneumotyphus respectively. In Ireland they are commonly called catarrhal typhus. In some epidemics laryngeal disease is very common. There may be simply reddening and swelling of the mucous membrane or suppuration may supervene. Not infrequently a unilateral perichondritis, which at times resulted in necrosis, was noted by Curschmann, and in fifteen per cent. of his Berlin cases lobar pneumonia was the immediate cause of death. This, however, is an inconstant factor, as is shown by the fact that Murchison rarely encountered it in England, and Thoinot and Netter make no mention of its occurrence in France.

Changes in the Circulatory Organs.—The chief changes in the circulatory organs are those on the part of the heart. Changes in the blood-vessels have been seldom observed. During the course of the disease unilateral dilatation and infectious myocarditis may be said to be of fairly constant occurrence, but other changes that have been noted in the appearance of the heart are unquestionably due to post-mortem influences.

Changes in the Muscles.—The muscles in general have a brownish-red and dry appearance. They show little sign of wasting. Small ulcerations have been frequently observed in the recti and thigh muscles, and the changes described by Zenker—atrophy of the fasciculi and granular and fatty degeneration—also obtain here, but to a less extent than in typhoid fever. Sometimes hemorrhages take place into the muscles.

Changes in the Liver and Spleen.—The liver is usually enlarged and soft. When death occurs after the ninth or tenth day the spleen is almost invariably found enlarged, if before this time it remains normal in size.

Changes in the Kidneys.—In severe cases the cortex is swollen, opaque, and has undergone more or less fatty change. Cloudy swelling of the epithelial cells of the convoluted tubules may also be seen.

Changes in the Gastro-Intestinal Tract.—Affections of the stomach and intestines are not frequent. Peyer's patches and the mesenteric glands are likewise rarely involved, and infiltration and degeneration are never found.

Symptomatology.

General Description.—*Incubation.*—The stage of incubation lasts for from one to fourteen days, oftenest eight to twelve. Reliable records inform us that its duration may be only a few hours, and that it is very rarely prolonged more than fourteen days. During this stage symptoms seldom manifest themselves. Occasionally a history of headache, loss of appetite, depression, and general inaptitude for work is given.

Invasion.—The outset is, as a rule, sudden. Repeated chills within the first twenty-four hours are common. The temperature rises quickly and may, on the first day, reach 104° F. Headache, pain in the back, and along the course of the larger nerve trunks are quite constant features. Prostration soon sets in, and even the most robust individual takes early to bed. The chills may recur for a few days, and are not infrequently accompanied by nausea and vomiting. The mind, which is at first clear, soon becomes clouded; the patient is uninterested in things about him, his talking is fragmentary, and his expression is dull and stupid. Mild delirium may set in, and in severe cases may develop into maniacal storms. The pulse is rapid, but full in volume; dicrotism is rare. The face soon shows a reddish flush, often a peculiar œdematous appearance, and the conjunctivæ are injected. The intensity of the color in the face is said to be an index of the severity of the disease. The tongue is dry, tremulous, and covered with a yellowish-brown coat.

On the third, fourth, or fifth day the rash appears on the skin of the abdomen. With its occurrence the temperature remains high and the symptoms in no way abate. In severe cases the heart may become enfeebled, respiration accelerated, and death may ensue from exhaustion. In more favorable cases the crisis occurs about the end of the second week, the patient often falls into a refreshing sleep and awakens with a clear mind.

Special Features and Symptoms.—*The Temperature.*—The fever rises steadily and may be 104° F. the evening of the first day. It continues to rise with but slight morning remissions for four or five days and reaches its maximum, 106 to 107 F., about the end of the seventh day. Having reached its height it continues with remarkable constance between 104 and 105 F. until the thirteenth or fourteenth day, when it falls by

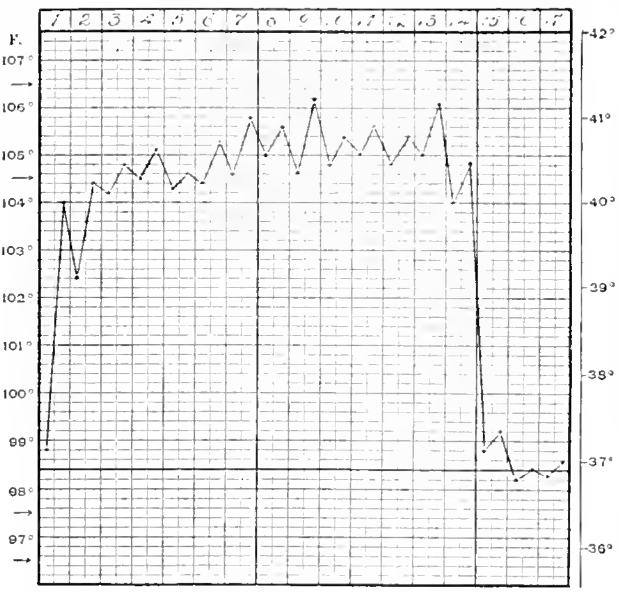

FIG. 4821.—Typical Fever Curve of a Moderately Severe Uncomplicated Case of Typhus Fever, Diagrammatic.

crisis. The crisis is one of the most characteristic features of typhus fever. The temperature may fall in a few hours from 105 or 106 F. to normal or slightly below. A longer time, however, is usually required, and there is frequently a rise of a degree or more before the normal point is reached.

Variations from the typical temperature curve occur, but not as frequently as in typhoid fever. In mild cases the temperature rarely rises higher than 103 F. Much importance has been attached by Wunderlich and his followers to a so-called characteristic drop in the fever on the seventh day, but it has been repeatedly shown that this symptom is the exception rather than the rule. The fever may reach its height within the first twenty-four or thirty-six hours. In many cases defervescence is protracted. This is more noticeable in mild than in severe cases. There are abortive cases in which the onset is severe and the crisis occurs on the fifth or sixth day. A rather remarkable feature, just before death, is the so-called pre-agonic rise to 109 or 110 F.

The Eruption.—Between the second and the eighth days, more frequently on the fourth or fifth day of the disease, the eruption first appears. Salomon[20] reports a case in which the eruption was delayed until the eleventh day. The spots come out first upon the abdomen, chest, and back, then upon the extremities and face. The sequence of the eruption, however, is by no means definite. It develops quite rapidly, so that by the end of the second or the beginning of the third day after its appearance it is all out. It does not come out in successive crops. The eruption is marked on the extremities. The flexor surfaces of the forearm are first involved. In many cases the spots are quite noticeable on the dorsum of the feet. The face is generally exempt, although in some epidemics the eruption on the face has been marked.

In the *stage of hyperæmia* there is at first a fine dusky red mottling just beneath the cutis. The spots soon appear as irregular rose-pink maculæ. They range in size from that of a pinhead to that of a lentil, and may be slightly elevated above the skin. At first they disappear completely when pressed beneath a glass slide later they become a dirty-red color, begin to undergo hemorrhagic change, and give up their color sluggishly when pressed upon. During the early part of this stage, particularly in dark-complected people, the eruption even in the best light may be difficult to see. In children the rash quite frequently resembles that of measles, and because of its peculiar mottled appearance has been called mulberry rash.

In the *hemorrhagic stage* "there is an infiltration of dissolved hæmatin into the tissues of the cutis." This change begins in the centre of the spot and extends to the periphery. The spots soon cease to be hyperæmic, the color only partially disappears on pressure. At first they are bluish-red and as the hemorrhagic change goes on they become a dark livid color. They are more numerous in the inguinal regions, or where the skin is loose. Sometimes the spots appear to be undergoing a true petechial transformation. Indeed, Murchison, Moor,[21] and many others describe the petechiæ as dark purple points in the centre of the spot, or speak of the maculæ being converted into petechiæ. Strictly speaking, these statements are not correct. Hemorrhagic changes that ordinarily occur in the spots must be distinguished from the true petechiæ.

The *petechial stage* is characterized by the occurrence of *direct* hemorrhages into the skin. These little bluish red spots do not disappear on pressure, and are not preceded by a stage of hyperæmia. They occur usually at the height of the disease, and are more common in some epidemics than in others. When they are present in small numbers no importance is attached to them; but when they are abundant and combined with extensive hemorrhages into the skin, they are of bad omen. Hemorrhages into the conjunctivæ are common during this stage. All these, together with the livid spotted body, present a most horrible picture.

The stage of eruption lasts for from seven to ten days, and traces may remain for several days longer. If hemorrhagic changes do not occur the primary rose spots remain but a short time. They may have all disappeared by the end of the first or the beginning of the second day. When the eruption is petechial it may last well into convalescence. The abundance of the eruption appears to be uninfluenced by age or the severity of the disease. It depends rather upon some unknown influence in the character of the epidemic. A peculiar "rotten-straw odor" is described by some authors as occurring during the stage of eruption. Littlejohn and Ker[19] noted it in the somewhat recent Edinburgh epidemic, and assert that it was of great help to them in diagnosis. Gerhard

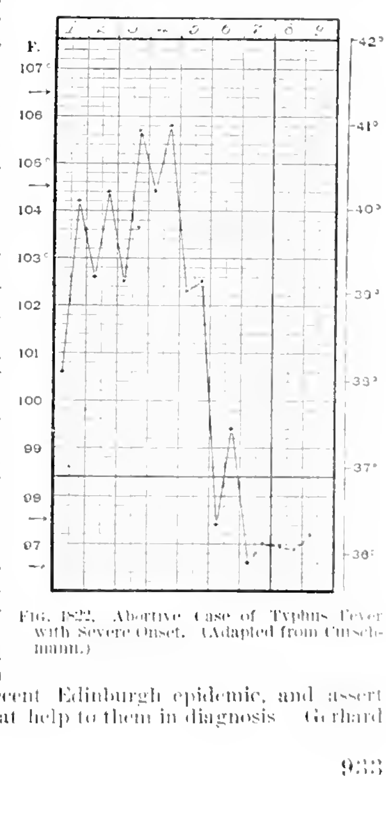

FIG. 4822. Abortive Case of Typhus Fever with Severe Onset. (Adapted from Curschmann.)

describes the odor as "pungent, ammoniacal, and offensive."

Other changes occur in the skin, among which may be mentioned herpes facialis, which is not infrequent, miliaria crystalina (sudamina crystalina), icterus, abscesses, and bedsores.

Nervous Manifestations.—Foremost among the many nervous manifestations of typhus fever is the early and pronounced prostration. The patient is quickly overcome by the intensity of the toxin and immediately takes to bed. Symptoms of nervous excitement often precede the prostration for a few days. He complains of severe frontal headache, pain in the eyes, vertigo, and pain in the sacrum. Insomnia soon becomes a prominent symptom; and if he does sleep, frightful dreams disturb him. Consciousness is maintained for some days, but sooner or later he grows dull and apathetic. Hallucinations of impending harm are very common. Toward the end of the first week the stupor increases, consciousness is finally lost, he mutters to himself, and picks at the bedclothes; there is subsultus tendinum. He may lie with his eyes wide open, unconcerned as to what takes place about him (coma vigil). Delirium of varying degrees is almost constantly present. Even after the temperature has returned to normal delirium may persist. Not uncommonly during the height of the disease, especially in young robust individuals, it takes on a maniacal form; they seek to escape from their terrifying hallucinations by suicidal attempts. On the other hand, depression may predominate. Among other nervous phenomena which deserve a passing notice are convulsions, hemiplegia, and meningitis. Sensory disturbances probably exist at times, but of this we have little definite knowledge.

The Blood shows few important changes; a moderate leucocytosis has been observed. The other changes are those of secondary anæmia—reduction of the red corpuscles and hæmoglobin. This is more noticeable during convalescence from a severe attack. No degenerative changes in the red cells have been observed. The serum does not agglutinate the bacillus typhosus. Little significance is now attached to the changes in the coagulability of the blood, described by the older writers.

Special Senses.—*Eye.*—Of the disturbances of the special senses those of the eye are perhaps the most prominent. Catarrhal conjunctivitis, and even in mild cases keratitis sometimes leading to the perforation of the cornea, and conjunctival hemorrhages may occur. In severe cases the pupils often become markedly contracted in the later stages of the disease; vitreous opacities and choroiditis, iritis and atrophy of the optic nerve have been observed.

Ear.—Disturbances of hearing are common. They usually occur during convalescence; very seldom when the disease is at its height. Hartmann found aural disease in forty-two of one hundred and thirty men during convalescence. The conditions most frequently met with are catarrhal inflammation of the Eustachian tubes and tympanic membrane, purulent otitis media, and perforation of the tympanum.

Renal System.—The ordinary febrile characters of urine are usually present. Retention is not uncommonly met with in women, but is rare in men. More or less definite changes occur in the solids. The chlorides are markedly diminished, and in the later stages of the disease it may be impossible to demonstrate them. Uric acid is almost always increased, but there is practically no variation in the percentage of urea. During the height of the disease there may be a transitory polyuria. At this time the urine is very pale. Albuminuria is common; when moderate it is of no significance. It may, however, be severe and accompanied by hæmaturia, epithelial and hyaline casts, and all the indications of parenchymatous change in the kidneys.

The diazo reaction, as has been pointed out by Vierordt and others, occurs with considerable regularity. Littlejohn obtained it in fifteen of his eighty-two Edinburgh cases. Gerhard's ferric chloride reaction is not infrequently obtained.

Generative System.—Orchitis is even more rarely met with in typhus than in typhoid fever. Menstrual changes are particularly common. The menses may be copious and appear prematurely; but if the disease develops soon after a menstrual period, menstruation may be suppressed until convalescence is well established. Pregnancy exerts no influence on the course of the disease; abortion is very uncommon. The fœtus may be infected (placental transmission), as has been described in the section on etiology.

Respiratory System.—Tracheal and bronchial catarrh occurs so frequently that it may be considered a part of the disease. It is present in the beginning and continues through the height of the disease. It manifests itself by frequent cough with slight expectoration of a glairy, sometimes blood-streaked sputum. Pneumonia and hypostatic congestion are among the not infrequent complications which involve the lungs. No cases associated with true diphtheria are to be found in the literature, though diphtheroid conditions are frequently mentioned. Laryngeal complications, such as swelling of the mucous membranes, erosions, fissures, and ulcerative changes in the cartilages, may also occur.

Digestive System.—Aside from the nausea and occasional vomiting which accompany the chills in the beginning of the disease there are no prominent symptoms referable to the digestive apparatus. It is thought by some that the tongue shows fairly constant characters. At first it is moist and is soon covered with a thick yellowish-brown coat; later it becomes dry, cracked and fissured, and tremulous. Sordes collect on the lips and teeth. There may be constipation or diarrhœa.

Varieties of Typhus.—Typhus fever is subject to many variations in its course. The older writers recognized four distinct forms.

1. Inflammatory typhus which occurs in robust young people and is characterized by headache, high fever, and delirium.

2. Ataxic or nervous typhus in which delirium, stupor, and subsultus tendinum are the most prominent manifestations.

3. Adynamic typhus, characterized by marked prostration, enfeeblement of the heart's action, and early tendency to collapse.

4. Ataxo-adynamic typhus, a term applied by Murchison to those cases which possess characters both of the ataxic and of the adynamic varieties. These forms, as it will be seen, are simply modifications of the ordinary form of typhus due to the prominence of certain symptom groups.

Ambulatory typhus has been considered very rare. Buchanan,[15] however, states that he has often seen the eruption out on patients who have walked to the London Fever Hospital; and there are other well-authenticated instances of this form. According to Griesinger and Wyss the greater number of cases of this form occur in young children.

Mild and Abortive Forms.—Mild forms of typhus are less frequent than in typhoid. In these cases the onset is generally mild. The fever is often irregular, and reaches the normal after many days. These are known as "*febris exanthematica levissima.*" In abortive typhus the onset is usually marked by a violent chill, and the temperature reaches its height by the end of the first or beginning of the second day. It continues with remissions for four or five days, when it drops by crisis, reaching the normal point within a few hours. (See temperature chart, page 933).

Malignant cases, whose duration may be rapidly fatal, occur. They are known as typhus siderans and blasting typhus. Subfebrile and afebrile cases have been reported.

Relapses and recurrences are not common; indeed it has been questioned whether relapses occur at all. Nevertheless a few undoubted cases have been reported. Buchanan records one among five thousand cases at the

London Fever Hospital and Curschmann two among his cases. Curschmann is inclined to regard his cases as anomalous.

DIAGNOSIS.—During an epidemic the diagnosis of typhus fever is not difficult. Unless isolated cases are typical and can be watched for a number of days until the eruption develops, it may be impossible to be certain of the diagnosis. There are a number of diseases which may be confounded with typhus fever. They are here given in the order of their importance:

Typhoid Fever.—The chief clinical differences between typhus and typhoid are to be found in the temperature and the eruption. The gradual step-like ascent of the fever in typhoid is practically never seen in typhus. The onset in typhus is sudden, the temperature reaching a high point within the first twenty-four hours. The morning remissions are very much smaller in contradistinction to those of typhoid. The temperature curve during the first week in typhus is so characteristic as to be almost pathognomonic. The defervescence in typhus, which never occurs later than the fifteenth or sixteenth day, is always by crisis. So all through the course of the disease it will be seen that the temperature maintains typical differences from that of typhoid. The development of the eruption on all parts of the body, and its tendency to become hemorrhagic, are so different from what occurs in typhoid as to leave little chance for error. However, we are not unacquainted with extensive eruption and the occurrence of petechiæ in typhoid. It is characteristic for the eruption of typhoid to develop in successive crops; such is not the case with the typhus eruption. Early appearance and prominence of psychic disturbances point to typhus. The diazo reaction obtains in both diseases, but the presence of the Widal reaction and the isolation of bacillus typhosus from the blood, urine, or stools are distinctive of typhoid.

Smallpox.—The onset symptoms in smallpox and typhus have much in common. There is very little difficulty in distinguishing between variola vera and typhus, as exactly opposite clinical manifestations are present at the beginning of the eruption in each. *Variola Vera:* Eruption on the fourth day, temperature normal or thereabouts, general symptoms abated. *Typhus:* Eruption variable, third to fifth day, temperature then at its height, general symptoms at their acme. It is often wellnigh impossible, on the other hand, to distinguish typhus from hemorrhagic smallpox—purpura variolosa—as in the latter there is a somewhat diffuse hyperæmic rash on the lower part of the abdomen and in the groins, which soon extends and undergoes hemorrhagic change. Small petechial spots and hemorrhages into the conjunctiva are also seen in this disease. The initial rashes in smallpox seldom confuse the diagnosis.

Measles.—While the catarrhal symptoms very frequently accompany the onset in typhus they are not so marked as in measles. The eruptive stage offers the greatest difficulties. In both the temperature is high and remains so after the eruption appears—the fourth or fifth day. The eruption develops rapidly, is macular, and of a rose-pink color. That of measles occurs first on the face, while in typhus the face is usually exempt. In the early part of the disease Koplik's sign and the crescentic arrangement of the spots in measles are very characteristic. A few days will always suffice to determine the diagnosis, for by this time the hemorrhagic changes begin to appear in the typhus spots.

Relapsing Fever.—Typhus and relapsing fever frequently exist together. Under these circumstances, for a time at least, the diagnosis is obscure. The early finding of spirilla in the blood and the later appearance of a rash speak for relapsing fever and typhus respectively.

PROGNOSIS.—Typhus fever is one of the most dangerous of the acute infectious diseases. The mortality is in direct relation to hygienic and sanitary conditions. It is lowest among those affected at large (ten per cent.); highest where only the poorest hygienic conditions are attainable. Under such conditions the death rate may be as high as fifty per cent. At the London Fever Hospital, for twenty-three years ending 1870, the mortality was eighteen to twenty per cent. Such symptoms as subsultus tendinum, pinhole pupil, coma vigil, and relaxation of the sphincters are exceedingly grave.

Among factors which influence the prognosis age stands foremost. The mortality is low under twenty, high between twenty and thirty, higher between thirty and forty, and highest after forty. The disease is almost always fatal in the intemperate. Other factors which influence the prognosis are weather and season, occupation, and individual predisposition. These have been sufficiently considered elsewhere.

PROPHYLAXIS.—As has been stated before, the prevalence of typhus fever is in direct relation to the efficiency of the sanitary conditions of the locality. "Its appearance in well-regulated civilized communities, where sanitary laws are observed, no longer occasions more than passing alarm." Public and personal hygiene must be carried out with the utmost precision and rigid quarantine instituted. There are three measures that demand more than passing consideration.

1. *Isolation.*—Under all circumstances patients should be segregated in well-appointed special hospitals. Expense is not to be spared by municipalities in establishing such institutions. History has shown us again and again that there is neither reason, philosophy, nor common sense in so doing, for here both patient and public are better served.

2. *Abundance of Air and Ventilation.*—In the warmer months these conditions are well met by placing patients out of doors in open tents. In hospitals the beds in wards must be so arranged that each patient has at least fifteen hundred to two thousand cubic feet of air. Free ventilation calls for the interchange of three thousand cubic feet of air per hour.

3. *Disinfection.*—Linen, urine, stools, cooking utensils, furniture, thermometers, or anything that has in any way, directly or indirectly, come in contact with the patient must be disinfected by the most rigid methods. None of these points should be slighted, the more so since we are entirely unacquainted with the specific cause of the disease, and whether it is present in urine, stools, or the exhalations. To accomplish this, carbolic acid, corrosive sublimate, milk of lime, formalin, and *fire* are necessary. Dead bodies should be cremated.

After recovery the patients should be detained in a detention ward for at least two weeks, and bathed frequently with warm water and carbolized soap.

TREATMENT.—The general management of typhus fever is the same as for typhoid. The patient's strength requires attention from the beginning. It is necessary, therefore, that the proper amount of nourishment be furnished. Nothing accomplishes this better than the milk diet employed in typhoid fever, and upon which so much has been written. It has been shown that the digestive processes go on more perfectly when patients are fed at frequent intervals. Systematic daily examinations of the stools for undigested particles should be made. It may be necessary to administer hydrochloric acid; indeed during the height of the fever it is good practice to give small doses—fifteen to twenty drops—as a means of stimulating the gastric secretion, which under such circumstances is decreased. Predigested foods are frequently indicated. Because of the large number of inert digesting agents on the market it is absolutely essential that one be used whose value has been recently tested and found up to the mark. Alcohol is to be given when the indications call for it, and coffee appears to have a beneficial effect upon the stupor.

The fever is best controlled by hydrotherapy. Its use in typhus has not been so general as in typhoid, partly because of the unfavorable circumstances which so frequently accompany epidemics of typhus, and partly because of an unfounded opposition on the part of members of the profession. There can be no question but that the mortality has been greatly reduced by this method of treatment. The statistics of Combemale,[22] while not as large as might be wished for, are nevertheless not without value. He found that with the expectant plan of treatment the mortality was 35 per cent.; that in patients who received two cold baths daily, after the specifications of Brand, it was 33⅓ per cent., and that among those who received six cold baths daily the mortality was reduced to 16.5 per cent. Curschmann advocates the use of hydrotherapy. He speaks favorably of the water-bed method. The patient is allowed to remain for hours, even all day, in water whose temperature is never carried below 68° or 70° F. The water can be conveniently changed from time to time without disturbing the patient. Curschmann employs the Brand method only in the most severe cases.

Among other hydrotherapeutic measures may be mentioned the cold sponge bath, cold packs and half packs, lukewarm baths, and the graduated full bath. For headache and psychic symptoms the ice cap will be found of great value. Whichever method of treatment is decided upon it must be carried out with great regularity.

The cold baths influence not only the fever, but all the resultant cerebral, circulatory, and respiratory symptoms. At times little decrease in the temperature is observed after the bath, but improvement in the general condition is always seen.

The open air treatment has already been referred to under prophylaxis, and has much to recommend it. Special nervous, circulatory, and pulmonary symptoms are managed the same as in typhoid fever.

Specific Treatment.—Little has been accomplished in the way of specific treatment. Legrain[23] tells certain of the beneficial effects of the serum treatment. He treated with success a number of cases in a prison by the injection of serum from convalescent typhus-fever patients. Chantemesse also reports success with this method. Because of the limited number of patients treated, little importance can be attached to these reports. It is unfortunate that more work along this line has not been done. It offers another field of research that has probabilities of fruitfulness.

Methylene blue has been considered to have some specific action in typhus fever. Nefedieff,[24] however, reports unfavorable results with this method of treatment. Other so called specific methods of treatment, as by carbolic acid, sulphocarbolates, and the sulphides, have proved to be of no value.

UKIAH VICHY SPRINGS.—Mendocino County, California

ACCESS.—Viâ San Francisco and Northern Pacific Railroad to Ukiah, thence a drive of three miles to the springs.

This pleasant resort, otherwise known as Doolan's Vichy Springs, lies nestled among enchanting hills, which fringe the boundary line of Lake and Mendocino Counties. This region has a combination of advantages which make it a natural sanitarium. From April to November the climate is delightfully balmy and the atmosphere is pure, clear, and invigorating. The scenery is of a pleasing and attractive character, and the neighborhood of the springs affords excellent fishing and gunning. The waters belong to the alkaline-carbonated class, and are clear and sparkling, with an agreeably pungent taste. Their chemical composition is not unlike that of the celebrated Vichy Springs of France (Grande Grille), and their physiological action on the human economy is practically identical with that exercised by those waters. Following is Anderson's analysis: One United States gallon contains (solids): Sodium chloride, gr. 28.60; sodium carbonate, gr. 195.52; sodium sulphate, gr. 0.36; potassium chloride, gr. 0.09; magnesium carbonate, gr. 19.75; calcium carbonate, gr. 18.14; ferrous carbonate, 0.07; silica, gr. 5.92; and traces of potassium carbonate, potassium sulphate, strontium carbonate, barium carbonate, lithium carbonate, borates, arseniates, and salts of alumina. Total solids, 268.45 grains. Carbonic acid gas, 224.75 cubic inches. Temperature of water, 93° F.

The French Vichy contains 408.95 grains per United States gallon. As an antacid, tonic, aperient, diuretic, and alterative mineral water the Ukiah Vichy ranks among the best in the country. It has proved highly beneficial in irritable states of the gastro-intestinal mucous membrane, dyspepsia, torpidity of the bowels, sluggish action of the liver, etc. Excellent results have also been observed in Bright's disease, acid states of the blood and urine, rheumatism, and gout. The waters are soon to be used commercially. There are numerous other springs on the premises, but their waters have not yet been analyzed. Good accommodations and bathing facilities are provided for visitors.

James K. Crook.

ULCER, ULCERATION.—The proper definition of the word ulcer, and exactly what limitations and restrictions should be placed on the term, have always been matters of considerable difference of opinion. Warren,[1] Curtis,[2] Tillmann,[3] and others follow with slight modifications the definition of Billroth, who defines an ulcer as "a loss of substance with no tendency to heal." Warren even goes further and says: "The term implies that the wound or granulation surface is stationary or enlarging, and that it has developed by death of the part piecemeal."

He further states: "An open granulating wound is not an ulcer, but it may become one if the granulations begin to break down and the edges begin to melt away." On the other hand, Park[4] defines an ulcer as "a surface which is or ought to be granulating," thus agreeing with Golding Bird,[5] whose definition is "a limited area of granulation tissue on the surface of the body."

Thus we have two absolutely contradictory ideas. If we accept the first definition, we must exclude all those ulcers which have begun to granulate in a healthy manner, and to which the name "healing ulcer" has been given; while if we accept the definition of Golding Bird, we leave out all those ulcers which are not granulating, such as rapidly spreading phagedenic ulcers, or those whose bases are formed by the underlying tissues (raw ulcer), or that condition known as croupous ulcer. Park, however, overcomes this difficulty by saying "is or *ought to be* granulating." Moreover, although a granulating wound cannot be distinguished pathologically from a healing ulcer, the term ulcer conveys a different impression; a definition which includes all cases would be: An ulcer is a solution of continuity or superficial loss of substance of the skin or mucous membrane which is, or has at some time been, progressively enlarging by inflammation. This definition would include all of the above-mentioned cases, and exclude healthy granulating wounds which have been the result of traumatism.

Ulceration is a word which by many authors is very loosely used. By some it is used synonymously with ulcer. Others employ the term where several ulcers exist, or where a considerable surface is the site of ulceration, as in ulceration of the rectum; but it seems better that the term should be restricted to the pathological process by which ulcers are formed, *i.e.*, a superficial molecular gangrene or disintegration of the skin or mucous membrane.

VARIETIES.—Since Bell,[6] as early as 1778, classified ulcers according to whether they were due to some local cause, or were symptomatic of some constitutional vice, his classification has with certain modifications been largely followed by subsequent writers. A satisfactory classification, however, is rendered difficult by the fact that there are often several etiological factors which may be present in any one case, as, for example, varicose ulcers where frequently traumatism, infection, phlebitis, periphlebitis, œdema, or eczema, either together or separately, may determine the formation or non-formation of an ulcer. Furthermore, an ulcer may be dependent on a certain poison acting in two different ways, either by primary infection or constitutionally, as in the initial lesion of syphilis and in tertiary syphilitic ulcers.

From an etiological standpoint ulcers may be divided into three great classes:

1. *Non-specific ulcers*, including all those cases not due to some particular infection or to malignant disease, but whose etiology depends on: (*a*) traumatism; (*b*) infection with some of the pyogenic or saprophytic bacteria; (*c*) interference with the circulation either of the arteries or of the veins or lymphatics; (*d*) interference with nutrition through the trophic nerves; (*e*) pressure from without as from splints, apparatus, or even the bedclothes, as in the case of bedsores; or from within as from benign tumors, gouty tophi, etc.; (*f*) skin diseases, as pemphigus, eczema, ecthyma, and herpes; (*g*) constitutional disease, as scurvy or diabetes; (*h*) the various causes of ulcers of the mucous membranes (excluding specific infection and malignant disease), as uræmia, mineral poisons, abdominal burns, etc.

2. *Specific ulcers*, including those due to: (*a*) syphilis; (*b*) tuberculosis; (*c*) typhoid; (*d*) diphtheria; (*e*) various forms of dysentery; (*f*) malaria; (*g*) glanders; (*h*) actinomycosis; (*i*) leprosy.

3. *Malignant ulcers*, among which are included superficial malignant new growths which break down and ulcerate, or deeper ones which involve and destroy the skin or mucous membrane overlying them. These malignant ulcers may follow the types of carcinoma, sarcoma, epithelioma, or rodent ulcer, being due to the breaking down of the primary growth, or an old chronic ulcer may become malignant by undergoing epitheliomatous or more rarely sarcomatous degeneration.

Besides this classification according to etiology, various names are given to ulcers depending on their condition at the time of examination. Thus we have:

1. Healing.
2. Spreading: (*a*) inflamed; (*b*) phagedenic; (*c*) sloughing.
3. Chronic: (*a*) with feeble, indolent or exuberant granulations; (*b*) with callous edges; (*c*) with a croupous base; (*d*) with a raw base. And in addition the terms fungating ulcer and scirrhous ulcer are sometimes used to describe ulcers due to malignant disease. By some authors these names depending on the condition of the ulcer are used as a basis of classification; but in reality they are only phases through which various ulcers may run during their course.

ETIOLOGY.

We have seen in considering the classification of ulcers that there may be several factors in the etiology of one of these lesions, or that one cause may act alone. The etiology may therefore best be studied by dividing it into:

1. Predisposing causes: (*a*) general; (*b*) local; and
2. Exciting causes.

1. PREDISPOSING CAUSES.—(*a*) *General — Age, Sex, Occupation, Social Condition, etc.* Age can hardly be considered as an important factor in the etiology of an ulcer, as there are so many other elements which have a more direct bearing on its causation. To be sure, old age is accompanied by retrogressive tissue changes, atheroma of the arteries, impaired circulation, etc., and one would therefore expect the statistics to show a greater proportion of ulcers during the later decades of life. But that ulcer is not relatively more frequent in the aged is probably due to the fact that such frequent causes as tuberculosis prevail in the early decades, and syphilis in early middle age, and also that traumatism in the early and middle decades is more frequent than among the aged. As regards sex, it has been shown by statistics that ulcer is three times more prevalent in men than in women. This is probably due to the fact that men are more exposed to traumatism, and that they are more likely to neglect a slight wound, which with infection becomes an ulcer. Also the greater prevalence of syphilis and alcoholism in men may in some measure explain why ulcers are more common among them than among women. Occupation seems to have little t do with the etiology of ulcer beyond the fact that it may predispose to traumatism or various forms of infection and that it may prevent cleanliness. It is in this latter element that we have one of the most important etiological factors in the causation of ulceration. The non-specific and non-malignant forms of ulcer are infinitely more common among the poorer classes, among whom lack of means or lack of intelligence, as well as untidy habits, will allow filth, and with it of course infection, to enter a wound the result of some slight abrasion, or the lesion of some skin disease; and the formation of an ulcer is the consequence.

Constitutional Disease.—Many of the constitutional diseases such as diabetes, lithæmia, scurvy, anæmia, tuberculosis, and syphilis, as well as the exhausting fevers, as typhoid, scarlatina, etc., lower the vitality of the tissues, while other conditions, such as valvular disease and fatty degeneration of the heart, general obesity, and atheroma, by preventing proper circulation predispose to the formation of ulcers when there is in addition some exciting cause.

(*b*) *Local Predisposing Causes*—1. *Interference with the Arterial Circulation.*—There may be a predisposition to ulceration as a result of embolism which cuts off the nutrition of a part, or the embolus may be infected and thus cause the formation of an abscess, which, if superficial, may result in the development of an ulcer. Atheroma of the blood-vessels, by interfering with nutrition, may also act as a local cause. Certain vaso-motor disturbances, such as occur in frost bite, chronic ergotism, and Raynaud's disease, may produce small areas of localized gangrene, and these areas may become subsequently the seat of ulceration.

2. *Interference with the Venous Circulation. Varicose Veins.*—When œdema results from interference with the return of venous blood from a part, it is obvious that such a condition would predispose to the formation of ulcers. The exact relation of varicose veins to the formation of ulcers is, however, a matter of dispute. There are many people who have varicose veins even to a severe degree, who never suffer from ulcer; consequently we must look for some other element in the etiology. Schreider[7] tried to prove this other element to be the gouty diathesis, and he considers both the varicose veins and the ulcers to be the result of lithæmia. Quénu[8] found a neuritis secondary to the varicose veins, and considers the formation of the ulcer to be due to trophic disturbance. In this view he is upheld by Silvy.[9] On the other hand, Mr. A. Pearce Gould[10] writes of "those troublesome ulcers of the lower third of the leg nicknamed varicose." There is one condition, however, which certainly has a direct bearing on the relationship of varicose veins to ulcer, and that is

phlebitis. Where phlebitis and periphlebitis occur, especially in the smaller venous radicles, small abscesses often form, the adjacent skin becomes involved, and an ulcer develops, or the rupture of the diseased wall of one of the

FIG. 4823. Ulcers due to Lymphatic Obstruction. (From Dr. B. Farquhar Curtis.)

small veins may, in the case of a person of uncleanly habits, readily prove the entering point of infection. Then, under the favoring influence of an impaired circulation in and poor nutrition of the part, such a rupture is not unlikely to end in the formation of an ulcer.

3. *Interference with the Lymphatic Circulation.*—Occasionally, in the treatment of extensive cellulitis, it is found necessary to make deep incisions, and the contraction of the resulting scar tissue may interfere with the lymphatic flow and give rise to stasis and thickening of the part. Under such conditions, and especially when they occur in the leg, ulceration is very likely to take place. A similar condition is found in elephantiasis (Fig. 4823).

4. *Trophic Changes.*—In the discussion of the so-called varicose ulcers, it has been mentioned that Quénu and Silvy believed the ulcer formation to be due to trophic changes. There are many other conditions, however, in which the relationship of ulceration and disease of the nerves or nervous system is more apparent. In infantile paralysis, in which the nutrition of certain parts is impaired by reason of the diseased condition of their centres in the spinal cord, all that is needed for the production of an ulcer is often a slight traumatism plus infection. Perforating ulcer of the foot is a frequent complication of locomotor ataxia. Also myelitis, peripheral neuritis, and other pathological conditions of the nervous system may, either through trophic changes or by reason of impaired sensation, be directly related to the formation of an ulcer.

EXCITING CAUSES.—*Traumatism, etc.*—One of the most frequent direct causes of ulcer is an injury of one kind or another. The degree of the injury may of course vary greatly, and whether or not it will produce ulceration depends on one or more of the predisposing causes already mentioned. A severe traumatism may be necessary entirely to destroy the vitality of a part in a healthy person; while a slight injury might do so in the presence of lowered vitality, constitutional disease, impaired circulation, trophic nerve disturbance, or where the amount of subcutaneous tissue between the bone and skin is slight in amount, as over the malleoli for example. Moreover, the nature of the traumatism may vary. The skin or mucous membrane may be destroyed by a contusion, laceration, friction, or a burn, so that it must heal by granulation. If healing occurs in a healthy manner at once, without any infection, we have a clean granulating wound. If, however, infection takes place and the wound becoming unhealthy extends by a process of molecular gangrene, then we have an ulcer. Pressure from within or from without may cause ulceration, mainly by the cutting off of nutrition and thus producing localized gangrene. As illustrations of ulcers caused by pressure from without may be mentioned bedsores, as also pressure sores from too tightly applied splints and badly fitting orthopedic apparatus. Ulceration may also be caused by pressure from within outward, as in the case of the end of the bone in faulty amputations, and in that of the growth of a benign tumor. In the same manner foreign bodies, such as deposits of biurate of sodium (gouty tophi), may result in ulceration of the overlying skin. Or the ulcer may be produced by the irritation caused by the presence of a foreign body beneath the skin, as in the case of a dracuncular ulcer caused by the filaria medinensis or guinea-worm.

Infection.—Roswell Park [4] says: "The idea underlying ulceration is infection, and when limited to its proper significance, the term should never be used for a process in which infection and consequent breaking down of tissues do not virtually comprise the whole process." The development of an ulcer from a clean granulating wound or abrasion usually depends on infection with some of the ordinary saprophytic or pyogenic germs. Or, in another class of cases, infection with consequent suppuration or gangrene of the skin resulting in ulcer formation, may take place through the circulation. Rapidly spreading ulcers, such as occur in phagedena and hospital gangrene, and some of the rapidly spreading forms of tropical ulcer, are usually due to some particularly virulent septic infection, acting on a weakened subject. The chancroid is also an ulcer depending for its existence on infection, whether it be due to the ordinary pyogenic germs, or to a specific bacillus, such as has been described by Ducrey, who found a rod-shaped bacillus with rounded ends in the secretion from chancroidal ulcers. In old chronic cases the bacteriological infection is of a mild type. Bukovsky [11] examined bacteriologically one hundred cases of ulcer of the leg, and found that the number of bacteria, even in foul cases, was much less than he expected, in many cases only a single species being found. The bacillus pyocyaneus was most frequently found. Other organisms found were the staphylococci, streptococci, B. coli, B. proteus, and (in a single instance) Friedländer's pneumococcus. Less interesting were the micrococcus albus, M. sulphureus, B. lactis aërogenes, B. mesentericus, B. subtilis, B. tumescens, and sarcinæ. On the other hand, certain definite forms of ulceration depend on infection with some specific germ or virus, *e.g.*, syphilis, tuberculosis, leprosy, typhoid, glanders, etc.

Syphilis.—This disease in its various stages is one of the most frequent causes of ulcer formation. In the primary stage the chancre is usually an ulcerative lesion. The ulcerative manifestations of secondary and tertiary syphilis may develop from a tubercular, pustular, or pustulo-crustaceous syphilide. But it is in the tertiary stage which, according to the statistics of Haslund,[12] develops in twelve per cent. of all cases infected, that we find the form which is most often spoken of as a true syphilitic ulcer. In this stage gummata form in the subcutaneous tissues or deeper parts, the overlying skin becomes involved and breaks down, the gumma due to its poor nutrition and deficient blood-supply sloughs out, leaving either the typical "punched-out" syphilitic ulcer or else a deep ragged ulcer with overhanging edges. In addition to the tertiary ulcer originating from a gumma, an obliterative endarteritis due to syphilis in its late stage may, by interfering with the nutrition of a part, predispose to ulcer formation.

Tuberculosis.—Ulcerative lesions due to infection with the tubercle bacillus are common both in the skin and in mucous membranes. In the skin they may be due to direct infection by the tubercle bacillus and they then take one of three forms: tuberculosis cutis, which is due to a local infection, but is part of a general tuberculosis; tuberculosis verrucosa cutis, which is frequently spoken of as anatomical tubercles or post-mortem warts, and is usually found in dead-house attendants, butchers, and those who have to do with animals; and lupus vulgaris. The fourth and most common form of tuberculous ulcer of the skin, known as the scrofuloderm, is due to indirect infection of the skin. It occurs usually in young subjects, most frequently in the neck, or over some group of lymphatic glands, or over a joint which has been the seat of tuberculous inflammation. Suppuration occurs in the infected part and the pus is discharged through a sinus leading to the surface, where a typical tuberculous ulcer develops. The same form of ulcer may develop from a deposit of tuberculous material in the subcutaneous tissues, quite independently of any gland or bone involvement, the tuberculous tissue breaking down and involving the overlying skin. There is still another ulcerative skin lesion which has been attributed to tuberculosis, but its exact etiology is still a matter of dispute; I refer to erythema induratum or Bazin's disease. Thibierge and Rayaut,[13] Colcot Fox,[14] and Philipson[15] believe it to be of tuberculous origin. Tenneson,[16] Leredde,[17] Audry,[18] and Johnson[19] came to the opposite conclusion. Whitfield[20] suggests that there are two diseases included under the same heading. On the mucous membranes tuberculous ulcers may occur as a primary lesion, but most frequently they are secondary to tuberculosis in some other part of the body, usually the lungs.

Other Forms of Specific Infection.—There are, besides tuberculosis and syphilis, several other forms of ulcerative lesions of the skin and mucous membranes due to specific infection. Glanders or farcy due to the bacillus mallei may be contracted by human beings from horses or mules. Soft nodules form in the mucous membranes (usually of the nose) or in the skin, and these rapidly break down, leaving ragged ulcers. The lesions of actinomycosis, or "lumpy jaw," due to the ray fungus, usually at an early stage become infected with pyogenic bacteria, suppurate and form abscesses which discharge by fistulæ, and if close to the surface form ulcers. A form of chronic perforating ulcer of the foot, known as "Madura foot," is caused by a fungus closely resembling the actinomyces. Leprosy due to the lepra bacillus, discovered by Hansen in 1874, is also an ulcerative disease, the ulcers being due to the breaking down of the leprous tubercles or to trophic nerve changes, or else they are caused by the fact that the impaired sensation prevents recognition of an injury.

There are many other specific infections which result in ulceration of the mucous membranes. Thus, for example, ulceration may be produced by the typhoid bacillus, the diphtheria bacillus, the amœba coli, the dysenteric bacillus of Shiga,[21] and, as has been recently reported by Haller,[22] the malarial plasmodium. (For further details with regard to these the reader is referred to the special articles on these subjects.) Two of the forms of intestinal ulceration are, however, of especial interest from an etiological point of view: the ulcers of the duodenum secondary to cutaneous burns and those described by Mathieu and Roux,[23] which are due to uræmia.

Skin Diseases.—Certain forms of skin diseases, such as herpes, especially when it occurs on the genitals, ecthyma, and pemphigus, where infection of the primary lesion occurs, and there is a lack of cleanliness, may result in the formation of ulcers. This is particularly so in eczema, where the inflamed, thickened, serum-infiltrated skin is easily abraded and apt to break down and form ulcers. The ruptured vesicles of eczema also make an excellent point for entrance of infection, and when eczema accompanies varicose veins of the leg, it is often very difficult to prevent ulcer formation.

Action of Drugs.—Besides the local escharotic effects of certain drugs, as an etiological factor in producing ulcers, some drugs produce ulceration of the mucous membranes by their elimination. Mercury by its elimination by the salivary glands may cause an ulcerative stomatitis; by elimination in the colon, an ulcerative colitis. Phosphorus, by causing a necrosis of the maxilla, may result in ulceration of the buccal mucous membrane.

Malignant Disease.—Primary new growths of the skin usually take the form of epithelioma, which may develop on any surface of the body where there is squamous epithelium. Nearly three-fourths of these neoplasms occur on the face and lips. Rodent ulcer, a form of epithelioma, nearly always is found on the upper half of the face. These lesions are ulcerative from the beginning. Sarcoma of the skin—viz., the melanotic form—does occur, but it is rare in comparison. Carcinoma and sarcoma may also produce ulceration by secondary involvement, as when by rapid growth and subsequent breaking down of growths lying close to the skin, the latter is destroyed, and an ulcer is established. In addition to these primary and secondary ulcerating neoplasms a chronic ulcer in an old person may undergo epitheliomatous or, more rarely, sarcomatous changes and become malignant.

Etiology of Regional Ulcers.—In addition to the varieties of ulcer already spoken of, we may mention here briefly the various forms of ulcerative stomatitis due to traumatism, infection, gastritis, and sprue, as well as to mercurial poisoning. Ulceration of the rectum also deserves to be mentioned here. Although it may be due to several causes, in a large number of instances it is due to tertiary syphilis, and especially to the breaking down of gummata. Tuberculosis, either primary or secondary to tuberculous deposits in other parts of the body, dysentery, acute proctitis, traumatism from hardened fæces or foreign bodies in the fæces, pressure from a polypus or from a displaced uterus in women—all these may be causes of ulceration of the rectum.

Fissures, or those forms of ulcer which occur at the junction of the skin and mucous membrane of the nose, mouth, or anus, and on the nipples of nursing women, may also be considered under this heading. Fissures at the angle of the mouth, due to tuberculosis, have been already mentioned under the name of tuberculosis cutis. In infants suffering from hereditary syphilis, fissures are frequently found about the mouth and anus. The usual form of fissura in ano, a small, extremely painful linear ulcer, ordinarily found near the posterior commissure, is due to abrasion with hardened fæces or to infection after scratching, or to the breaking down of a herpetic vesicle. Ball considers anal fissure to be due to a broken-down anal valve. The lesion is prevented from healing by the movement of the sphincter at defecation and the turning in of the edges of the ulcer. Fissures of the nipples are due to infection following an abrasion or injury caused by the infant's nursing, and are prevented from healing by motion of the part.

Pathology.

The pathology will vary somewhat with the conditions causing the ulcer, although in the non-specific forms of ulcer we shall find the phenomena of congestion, exudative and necrotic inflammation, together with reparative inflammation or granulation, making up the whole process. In the stage of development of the ulcer the degenerative process predominates, in the healing stage the reparative.

When the ulcer develops from without, as when infection enters the skin through an abrasion, or through a wound of a different character, congestion first occurs. This is rapidly followed by the emigration of leucocytes, by a diapedesis of red blood cells which rapidly disintegrate, and by an exudation of serum and fibrin. At the same time there is a proliferation of the epithelial cells of the rete mucosum lying on the papillary layer of the corium, and also a proliferation of the connective-tissue cells of the corium. The tissues next become softened by the exudate between the cells. Then, as a result of the pressure of the exuded serum, of the crowding by the leucocytes, and of the cutting off of the blood supply, and also in some measure through the effects of the toxins furnished by the bacteria, there occurs necrosis or death of the cells, which are thrown off from the surface with the products of exudation, until there is formed an ulcer with its base consisting of spheroidal and a few epithelioid cells developed from the connective-tissue cells by proliferation.

The process of molecular gangrene just described does not represent the only way in which an ulcer may form; it may develop from a blister, by the sloughing away of an area of localized gangrene, from an infected wound with loss of substance, by the destruction of the skin over a superficial abscess, or by pressure from within. After its formation it may heal, continue to spread, or become chronic.

If an ulcer in its complete stage of development be examined, it will show the following pathological condition: The surface is covered with a layer formed by the overproduction of new round cells, together with the exudate of serum, fibrin, and the cellular elements of the blood. When the discharge from the ulcer is profuse, this may be constantly washed away. When the ulcer is sluggish, it may be in a condition of coagulation necrosis. In this condition a croupous material covers the base of the ulcer, and below this is a more or less distinct layer largely composed of cellular elements, with very little intercellular substance, the cells being spheroidal and epithelioid in character and mingled with polynuclear leucocytes. As we go deeper, the amount of intercellular substance increases, and we find a number of transparent fibres and fusiform cells. In this layer of granulation tissue are also the newly formed blood-vessels, the most superficial branches being vertical to the surface, and developing by a process of budding from the endothelial cells of the capillaries deeper down. This layer is paler in color than the layer made up of the cellular elements, but may contain pigment from the disintegration of the red blood cells. It gradually merges into a layer of cicatricial connective tissue which lies beneath the ulcer. A section of the edge of a chronic ulcer would show an enlargement and prolongation of the papillæ, with a marked proliferation of the epithelial cells covering them. This is most marked in the condition known as callous ulcer, where the edges may by this proliferation be considerably raised above the level of the surrounding skin, and often overhang the base of the ulcer, as if nature were trying to bridge it over.

Under proper treatment the reparative process proceeds faster than the degeneration of the cells and the ulcer begins to heal by granulation. Small sprouts or buds of protoplasm protrude from the capillaries below or in the base of the ulcer, developing from the cells in their walls. These are hollowed out by the blood pressure and form new blood-vessels which anastomose with others. Nuclei form in the protoplasm and thus endothelial cells develop. At the same time small spheroidal cells developing from the connective-tissue cells become grouped around the blood-vessels. These at first are closely crowded together, being only separated by a small amount of fluid intercellular substance. Some of the round cells then become larger and fusiform or branched. The larger cells are known as epithelioid cells. Some of the fusiform and branched cells, called fibroblasts, develop the new delicate fibrillar intercellular substance, while others form the connective-tissue cells. Gradually the fibrous intercellular substance increases in amount, while the cells become fewer and flattened, and cicatricial tissue is formed. The contraction of this cicatricial tissue constitutes an important element in the healing of an ulcer.

During the process of granulation, more of the round cells are produced than is necessary. These die and are thrown off in the discharge. Healthy granulations should be small, even, and of a reddish-pink color. Where the growth of the blood-vessels proceeds more rapidly than the development of the cells and the formation of connective tissue there is produced a soft, pale, flabby condition known as exuberant granulations. On the other hand, both the cells and the blood-vessels may develop very slowly, forming indolent or sluggish granulations.

In order that the ulcer may heal it must eventually become covered with epithelium, and this (unless grafting is practised) can only develop from the epithelium at the edges of the ulcer. Under favorable conditions, when the granulations reach the level of the surrounding skin, the epithelium begins to spread in a thin bluish-white line from the edges, out over the surface, until it is entirely covered, when the ulcer is healed. The rapidity of this process differs in different cases. Deutsch[24] measured one hundred healing ulcers, exclusive of traumatic cases, and found the average growth of epithelium to be from 2 to 3.5 mm. per week. The influence of contraction of the base of the ulcer, however, must also be taken into account.

The scar left by the healing of an ulcer is always considerably smaller than the original lesion, due to contraction of the cicatricial tissue, and this contraction, especially when the ulcer has occurred on the face, may lead to considerable deformity. The healed surface differs from normal skin in the absence of hair follicles and of sebaceous and sweat glands. In the mucous membranes, on the other hand, regeneration to a condition more nearly approaching normal occurs.

Modifications of the Course in Special Forms of Ulcer.—The pathological condition which has been described above applies to the simple forms of ulcer; but it practically forms the basis of all cases of non-specific and non-malignant ulcer with certain modifications due to the conditions present and to the etiology. These pathological changes are found not only in the ulcer itself, but also in the adjacent tissues. When an ulcer becomes acutely *inflamed*, a condition of cellulitis exists in its base and edges and in the tissues surrounding it. In a *spreading* ulcer there is little or no attempt at a reparative process, while degeneration and death of the cells proceeds rapidly. This may occur to such an extent in *phagedenic* or *sloughing* ulcers that we find, in addition to a process of molecular gangrene, considerable areas of necrotic tissue in the base and edges of the ulcer. In certain chronic cases there may be very little or no formation of granulation tissue, and the base would then be formed by the underlying body tissues instead of the layer of round cells already described. This condition is known as *raw* ulcer. In other cases the base may be smooth and shining like mucous membrane, or may be covered with a *croupous* layer formed of the material exuded. In *scorbutic* ulcers the base is covered with an adherent spongy, fœtid, dark-colored crust, and bleeds very easily.

In the case of *varicose* ulcers there is usually more or less pigmentation of the surrounding skin. Often œdema of the skin and subcutaneous tissues, and in many cases eczema, is present. When the latter occurs there is apt to be more than one ulcer. The veins are dilated, thickened, and tortuous, and show marked insufficiency of their valves. These changes are more marked in the superficial than in the deep veins, and cases vary as to whether the dilatation of the larger veins or that of the smaller radicles forms the more prominent feature. The walls of the veins become the seat of a phlebitis, which may be suppurative in nature, producing a periphlebitis, and thus frequently, by involvement of the skin, causing the formation of a new ulcer. The arteries may show an endarteritis. The nerves, as previously mentioned in connection with the etiology, show the signs of chronic neuritis. In old, chronic cases the connective tissue, muscles, and even the underlying periosteum and bone may be affected by a chronic productive inflammation.

Syphilis.—The pathology of syphilitic ulcers differs from that of the cases previously described, in that the ulcerative process is preceded by a productive one. In the chancre we have first an infiltration of the connective tissue at the site of the lesion with small spheroidal cells and an occasional giant cell, together with a proliferation of the connective-tissue cells. This breaks down and ulcerates at the surface. The superficial ulcers of the late secondary or of the tertiary stage are preceded by a round-cell infiltration, which may break down at once and form a pustular lesion from which an ulcer develops, or one or more tubercles may form which then break down. It is by the spreading and marginal growth of one of these tubercles or the progressive involvement of others, while healing is going on at one part of the ulcer, that the serpiginous ulcer forms. The deep ulcers of tertiary syphilis develop from gummata. These are variously sized deposits, largely made up of small spheroidal cells with some polyhedral and occasional giant cells. They are poorly supplied with blood-vessels and undergo coagulation necrosis, but do not tend to suppurate until infected. Sooner or later the overlying skin becomes involved, either with or without a secondary pyogenic infection, and the gumma then sloughs out, leaving the typical syphilitic ulcer. A bacillus, which has been described by Lustgarten,[25] and which is very similar to the tubercle bacillus, is found in small numbers in the lesions. Lustgarten was unable to cultivate it artificially. Van Niessen,[26, 27], however, succeeded in cultivating from the blood of syphilitics and from the discharge from syphilitic condylomata a bacillus which when inoculated on monkeys developed a primary lesion and general glandular enlargement similar to those seen in man.

Tuberculosis.—The gross pathological condition of ulcers due to tuberculous infection varies greatly, depending on the variety of the lesion. It may take the form of discrete, shallow ulcers as in tuberculosis cutis, or that of the ulcerative warty lesion of tuberculosis verrucosa cutis. Lupus vulgaris, characterized by its brownish red, semi-translucent, smooth, shiny, apple-jelly-like tubercles, also due to tuberculosis, may form an ulcerative lesion, but the non-ulcerative form is more common in this country. Erythema induratum begins as a varying-sized nodule under the skin which subsequently breaks down. The forms mentioned above, together with the irregular ulcer with livid overhanging edges, known as the scrofuloderm, the origin of which has already been mentioned, show how great a variety exists in the gross pathology of tuberculous ulcerative lesions. The minute pathological examination, however, shows all of these forms to be dependent on the formation and subsequent breaking down of tubercle tissue. The latter may be localized, forming miliary tubercles, or it may be diffuse. The tubercle bacillus and its toxins cause a productive inflammation, with proliferation of the connective-tissue cells, the tubercle tissue thus being made up of small spheroidal or polyhedral cells, or of the latter together with a fibrous stroma and cells resembling leucocytes, or of giant cells. At times the tubercle tissue very closely resembles granulation tissue. There is very little production of new blood-vessels, and the tubercle may undergo coagulation necrosis and caseous degeneration. The process may cease by encapsulation of the lesion with fibrous tissue, but the most frequent course is that in which the lesion breaks down, either as a result of secondary infection or directly without the intervention of infection. The pus which is formed as a result of this breaking down finds its way to the surface, along the course of least resistence, and gives rise to the scrofuloderm.

Neoplasms—Malignant Degeneration.—When an ulcer occurs as a result of a benign tumor, the cause being pressure, the pathological process is similar to that of the simpler forms of ulceration, although in some cases, as for example in cystadenoma of the breast, the rapid growth of the tumor may cause the tissue of the new growth to form the base of the ulcer. When, however, the ulcer is a result of malignant new growth, whether primary or secondary, the ulcerative process is due to a breaking down of the cells forming the new growth and an involvement of the adjacent structures with cancer cells. There may also be more or less production of granulation tissue. Primary malignant ulcers may be due to sarcoma, but far more frequently they are of the epithelial type—carcinoma, epithelioma, or rodent ulcer. Both sarcoma and carcinoma may secondarily involve the skin and produce ulceration. The former has a markedly less tendency to do so than the latter, but sarcomatous ulceration, when it does occur, is apt to take on the characters of the fungating variety. In all of these malignant ulcers the base and edges are made up of the cells of the neoplasm. For the minute pathology the reader is referred to the articles on *Carcinoma*, *Sarcoma*, and *Epithelioma of the Skin*.

Old chronic ulcers, especially in elderly patients, may undergo epitheliomatous degeneration and become malignant. This process, when it occurs, begins in the edge of the ulcer, taking its origin in the epithelial layer of the skin, and by its growth both base and edges of the ulcer become formed by the malignant epitheliomatous tissue, and the appearance then presented is that of a foul, hard, warty, easily bleeding ulcer. Sarcomatous degeneration of a chronic ulcer has also been reported. Here the new growth takes its origin in the connective-tissue cells instead of the epithelium.

Symptoms and Course.

Non-specific Ulcers.—The appearance and symptoms of the various non-specific ulcers will vary with the etiology of the ulcer and the pathological condition present at the time of examination. These differences will manifest themselves in the shape and size of the ulcer, in the appearance of the base and edges, in the character of the discharge, and in the condition of the surrounding tissues.

Acute Traumatic Ulcer.—When an ulcer is formed as a result of infection of an area where the skin has been destroyed by some form of traumatism, the symptoms are those of an acute inflammatory condition. The base of the ulcer is usually only slightly depressed, and is of a gray or dirty-yellow color, or sloughing in appearance. There are few or no granulations, the edges are clean-cut, soft, and inflamed, the surrounding tissue is red and congested, and the discharge is thin, sero-purulent, or blood-stained and containing débris. The shape of the ulcer will vary with the nature of the traumatism. These cases are accompanied with more or less pain. Such an ulcer may begin to granulate and heal, may spread or become chronic; and these conditions, which are more or less common to the various forms of ulcer, subject to modification depending on the etiology, will next be described.

Granulating or Healing Ulcer.—All ulcers which have reached the healing stage, irrespective of their cause, present practically the same appearance. The shape is round, or that of the original injury. The base is of a light-red color, even with the edges, or slightly depressed, not tender, and showing no evidence of hemorrhages. It should be covered with medium sized, regular, even granulations. The edges are soft, shelving, not thickened, and marked by a bluish-white border of newly formed epithelium, which is spreading over the surface of the ulcer from the epithelium of the skin, and will finally cover the surface. The peculiar bluish white color of this border is due to the presence of new blood-vessels which show through the translucent young epithelial cells. The surrounding area is soft, and not inflamed. The discharge is slight in amount and consists of a thick yellowish purulent material which is really not pus, as it is not the result of the death of leucocytes in an effort to combat infection; it is due rather to the throwing off, from the surface, of the unnecessary cells formed as a result of overproduction. The discharge is not very irritating and contains very few bacteria. An ulcer in this stage is not painful.

Spreading Ulcer.—Either from the start or later, as a result of a new infection or of some other complication, an ulcer may begin to increase in size. Its shape becomes irregular. The base is uneven, is gray or of a dirty-yellow color, and may be blood-stained. The process of degeneration is greater than that of repair, and there are no granulations. The edges may be thickened, by reason of the presence of an inflammatory exudate that forms while the ulcer is spreading slowly, or thinned out and undermined, on account of the rapidity with which the ulcer is spreading. The discharge is increased in amount, is thin, semipurulent, contains more or less débris thrown off by the rapid death of tissue, and is often foul and irritating. When such an ulcer becomes inflamed, the base, edges, and surrounding tissues become red, congested, and the site of a cellulitis. Often phlebitis, periphlebitis, and acute eczema are present. There are pain and throbbing in the part, and the discharge becomes profuse, purulent, and often blood-stained.

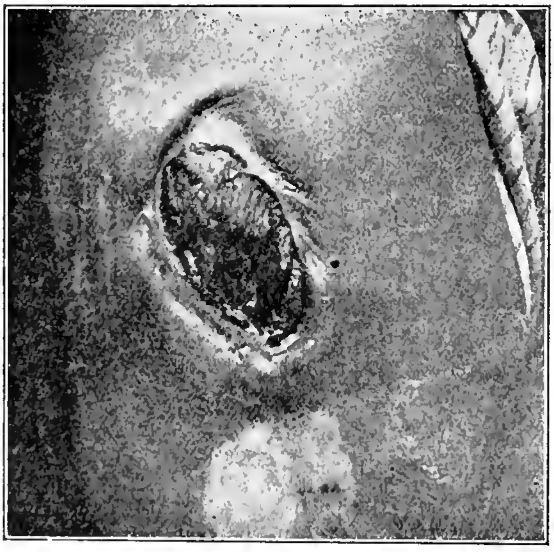

FIG. 4824.—Chronic Traumatic Ulcer, showing Raw Base, Absence of Granulations, and Thickened Adherent Edges.

The variety of spreading ulcer, known as *sloughing ulcer*, is particularly apt to occur in old persons of low vitality, with senile leg ulcers that have developed after exposure. The base is irregular and covered with sloughs or even with small areas of gangrene. There are no granulations. The edges are irregular, excavated, sloughing, and necrotic, or may be gangrenous in small areas. The discharge is profuse and foul, and contains the products of necrosis. Those very rapidly spreading cases, known as *phagedenic* ulcers, are fortunately, since the development of aseptic surgery, rare. They occurred in hospital gangrene, in some cases of venereal infection, and were more apt to be found in tropical climates, and where the patient was weakened by fever and disease. A severe grade of infection acts as the exciting cause. The base is irregular, sloughing, and covered with a grayish, fœtid, pulpy material. There may be large areas of gangrene. The edges are thinned out and undermined, the subcutaneous tissues disappearing before the skin, and are often gangrenous in places. The discharge is very foul and irritating.

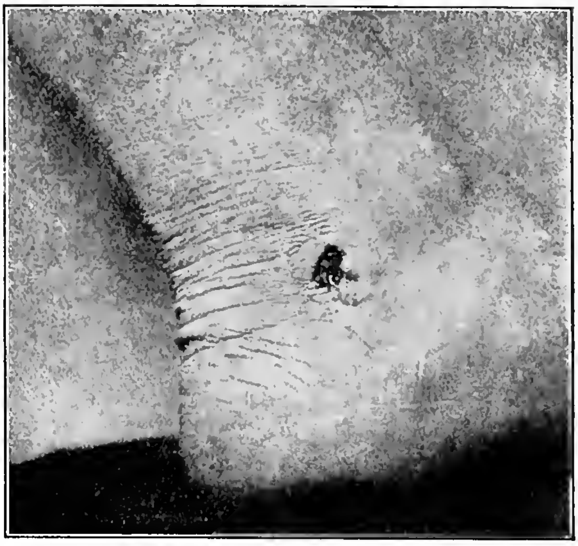

FIG. 4825.—Typical Erethistic Ulcer, showing Usual Situation and Appearance.

Chronic Ulcer.—Any ulcer may, from a variety of causes, fail to heal and become chronic. The most usual position, however, in which these ulcers are found is on the inner side of the lower third of the leg. They show great variety in size, shape, and appearance of base, edges, and surrounding area, and in accordance with these differences many different names are applied to them. The size varies from the small ulcer less than 1 cm. in diameter, sometimes found with varicose veins, to the large ulcers which surround the leg, and which are called *annular ulcers*. They may be round, very irregular, or funnel shaped, as in *perforating ulcer of the foot*. The base may be much or slightly depressed, or the granulations may be at a higher level than the surrounding edges. When the granulations are large, irregular, and bleed easily, they are spoken of as *exuberant* or *fungating;* when pale, soft, and flabby, as *weak* or *œdematous;* when small and slowly growing, as *indolent* (Plate LVII., Fig. 5). Sometimes the base is covered with a grayish or yellowish-white necrotic layer formed of fibrin and necrotic cellular elements. When this layer is removed no granulations appear, but instead a smooth shining base resembling mucous membrane. This form is known as the *croupous ulcer*. In some cases the base of the ulcer is formed of the body tissues (muscle or connective tissue), and the lesion may look like a fresh injury. These are called *raw ulcers*. The base of a chronic ulcer may be pigmented. The edges also vary greatly. They may be irregular or sharply cut, moderately thickened, or very much so, due to chronic congestion and œdema, with enlargement of the papillæ and proliferation of the epithelial cells. When this is a prominent feature the name *callous ulcer* is applied. The edges may be adherent to the deeper structures and thus prevent contraction and healing (Fig. 4824); they may be rounded, elevated, undermined, or overhanging. Usually they are of a uniform height, rarely worm-eaten. When a chronic ulcer shows no tendency to heal it is never shelving, and there is an absence of the bluish-white border, mentioned in connection with healing ulcer. The discharge from a chronic ulcer is usually slight in amount, serous in character, and contains very few pus cells. The surrounding area may be swollen, red, congested, œdematous, eczematous, pigmented, or the ulcer may be surrounded by smaller ulcers, vesicles, or masses of varicose veins. As a rule there is an absence of severe pain accompanying chronic leg ulcers, unless there is an exposure or involvement of some nerve filaments. But frequently, after the patient has been on his feet for a long time, there is a dull aching sensation in the part, due to chronic congestion, which causes tension in and about the ulcer.

A peculiarly painful form of chronic ulcer is found over the inner malleolus, most frequently in women of middle age, although it also occurs in men. It is often associated with varicose veins, and in women with menstrual disorders. It is known as a *congested, irritable*, or *erethistic ulcer* (Fig. 4825). These ulcers begin as a small area of congestion over the internal malleolus. This area gradually increases in size, and becomes darker and more dusky in the centre, due to a deposit of blood pigment caused by the chronic congestion. The skin next becomes hard, dry, scaly, and pigmented, while the subcutaneous tissues lose their elasticity, becoming inflexible, hard, and adherent to the deeper structures. Then, as a result of slight traumatism or even without injury, the centre of the area breaks down and an ulcer develops. It may be circular or irregular in shape; it may be quite deep or superficial. The edges are sharply cut, and both base and edges are tightly bound down to the deeper tissues. The intense pain characteristic of these ulcers is supposed to be due to pressure upon the terminal nerve filaments in the dense sclerotic tissue. This form of ulcer is often very difficult to cure, and shows a tendency to return after healing.

Varicose Ulcer.—To chronic ulcer of the leg associated with varicose veins, especially of the smaller venous radicles, the name varicose ulcer has been given (Fig. 4826). Such an ulcer occurs most frequently on the lower or middle third of the leg. In shape it is usually irregular, but when it has existed for some time it may become round. The size varies from the small ulcers less than 1 cm. in diameter, formed by the breaking down of an area of periphlebitis around a small vein, to those several inches in diameter. Several ulcers may be present on one limb. The base is irregular, bluish, and pigmented. It may closely overlie an inflamed vein, the rupture of which may cause a severe hemorrhage. The granulations of the base of a varicose ulcer are apt to be weak and flabby. The edges are irregular, undermined, and bluish. Two or more ulcers may become connected by undermining of the skin between them, the skin subsequently melting away so that only one irregular ulcer remains. After a varicose ulcer has existed for a considerable time, the edges may become callous. The discharge is thin, serous, mixed with débris, and may be blood stained. The skin surrounding a varicose ulcer is often of a brownish-blue color, due to a deposit of pigment. Frequently in a leg in which there are varicose veins, or which is œdematous from other causes, attacks of acute eczema occur. The vitality of the part is lowered by the impaired circulation and by infiltration of the tissues with serum, and as a result of infection of the vesicles, often by scratching, numerous small or large *eczematous ulcers* are formed in an area of hot, red, moist, itching, inflamed skin.

Perforating Ulcer.—This variety of ulcer may occur over the fingers or toes, but is most frequently found on the sole of the foot over the head of the metatarsal bones, especially the first. They usually occur in men over forty years of age, and are often associated with, and believed by many to be due to, some pathological condition of the nerves or nervous system; either to trophic disturbance, as in locomotor ataxia, or to impaired sensation. Tomaszewski[28] believes that they are not always due to impaired sensation and trauma, but that an isolated sclerosis of the plantar arteries plays a part in the etiology. This element might account for their presence in diabetes and late syphilis. A perforating ulcer of the

FIG. 4826.—Varicose Ulcer of the Leg, showing Multiple Lesions and Irregularity of Edges and Base.

foot usually begins by the formation of a small abscess beneath a mass of callous skin overlying the head of one or more of the metatarsal bones, the abscess being due to the trauma of walking and pressure. Frequently not much attention is paid to it on account of impaired sensation. Then the bone becomes involved, undergoes a rarifying osteitis, and breaks down. The callous skin over the abscess then sloughs and disappears, and there is left a painless, funnel shaped ulcer, extending down to the dead bone, which, together with a few reddish, warty granulations, forms the base of the ulcer. When a perforating ulcer has existed for some time, the epithelium grows down the sides, often almost to the bottom, lining the inner surface of the "funnel." This, together with the existence of dead bone at the base, makes these ulcers very hard to heal. The discharge is foul, purulent, and may contain fragments of dead bone.

Gouty Ulcer.—An ulcer may form as a result of the infection and breaking down of gouty tophi. It is usually irregular in shape, and may be elevated. The edges are thin, or, if the ulcer is old, they may be thickened. The base is made up of indolent granulations when the deposit of biurate of soda has been discharged; or, in the fresh ulcer, there may be deposits of sodium biurate in the walls and base of the ulcer. The discharge is a thin purulent serum containing needles of biurate of soda.

Scorbutic Ulcer.—In severe cases of scurvy there is a marked tendency of the skin to ulcerate, not only as a result of breaking down of the subcutaneous indurated swellings which are a symptom of the disease, but also under other circumstances, as when a previously existing sore, a fresh abrasion, or even an old scar becomes the site of a rapidly spreading scorbutic ulcer. Such an ulcer is characterized by a spongy, dark-colored, fœtid, adherent crust, the removal of which causes considerable bleeding, leaving a base covered with large livid granulations. The edges are swollen, tumid, and sharply cut. The discharge is a profuse, foul, sanious pus.

Diabetic Ulcer.—Diabetics suffer from a number of skin lesions. They are liable to carbuncles, furuncles, eczema, and acne; and, owing to the poor circulation, lowered vitality, endarteritis, and the circulation of abnormal products in the blood, they sometimes become the subjects of gangrene. Any of these lesions may result in an ulcer. When an ulcer occurs in a diabetic it is apt to be sloughy and to spread rapidly. The skin around it is often red and inflamed, and the ulcer as well as the surrounding tissues may be the seat of a cellulitis.

Tropical Ulcers.—There are several varieties of ulcer which are peculiar to certain parts of the tropics. They usually derive their names from the locality in which they occur. Other tropical ulcers, such as dracuncular ulcer, are named according to etiology.

Penjdeh ulcer, also known as Delhi, Lahore, and Kandahar sore and a variety of other names, occurs in India, Central Asia, the Levant, Algeria, and the Malay peninsula. It usually appears on some exposed surface of the body, as one or more papules, which develop into boils and then undergo slow ulceration. The ulcers are usually oval in shape. They may develop rapidly, and several ulcers may merge into one, with a ragged, thickened edge surrounded by an areola of inflammation. The base of the ulcer may be smooth, but is usually uneven, healing at one place and breaking down at another. The ulcer runs a very chronic course, lasting sometimes for months, and is at one time painful, at another not. When it shows a tendency to heal a crust forms, which has to be removed daily to allow healing to occur. It leaves a scar which is depressed, puckered at the centre, and pigmented of a bluish-brown color. According to R. H. Firth,[29] although there has been a want of uniformity in the results of the study of the etiology by different observers, we are warranted in saying that there are found in all cases, especially in the epithelial cells, certain coccoid bodies that stand in direct causal relation to the morbid process. Nearly all observers have attributed the Oriental sore to the domestic water supply.

Annam ulcer is a form of phagedena which occurs in Annam, Yemen, Aden, Cochin China, and Mozambique. B Scheube[30] believes that all the cases of this form of phagedena described as occurring in these regions are identical. It usually begins on the foot or leg with an area of infection. This area sloughs and the ulcer grows more or less rapidly, preceded by an area of inflammation. The base is made up of unhealthy granulations, which bleed very easily. The surface is covered with a foul pus or a grayish pseudomembrane. The edges are undermined. The base and edges of the ulcer may be gangrenous to such a depth as to expose to view the underlying tendons and muscular tissue. In some cases the muscle may also be gangrenous. The ulcer is very painful. Syphilis, anæmia, poor general condition, bad hygiene, and poverty, are believed to create a predisposition to the disease. The lesion is very difficult to heal.

Gaboon ulcer, described by Gaucher,[31] is a form of tropical ulcer found in the natives of Gaboon. It occurs on the limbs and is similar in appearance to syphilitic ulcer, especially in the character of the scar. It is not improved by treatment with antiseptics, but is most amenable to treatment with hot water.

Dracuncular ulcer is endemic in parts of India, Bokhara, Turkestan, Arabia, along the coast of the Red Sea, tropical Africa and parts of tropical South America. The ulcer is due to the filaria medinensis or guinea-worm, a species of thread worm, averaging three feet in length, but which may be as long as six feet. Its habitat is in the subcutaneous tissues. As the worm approaches maturity, she (for only the female is known) works her way toward the surface, usually downward to the leg, foot, or ankle, in order to discharge her eggs. When she reaches the derma, she pierces it and forms a bulla beneath the epidermis. This becomes infected, the skin breaks down and discloses an ulcer with a small hole in the centre, from which part of the worm may project. Usually in about two weeks the worm has emptied her uterus, and can be gradually extracted by gentle intermittent traction. According to Patrick Manson[32] the formation of the ulcer can sometimes be avoided by the injection of 1 in 1,000 bichloride of mercury into the tissues as soon as the parasite begins to irritate the skin. This kills the worm and it becomes absorbed like a piece of aseptic catgut.

Veldt sore is a form of ulcer occurring in South Africa. It was common among the British troops campaigning there, especially the cavalry and artillery branches of the service. It is least common in cold weather and high altitudes. Most frequently the sores are found on the exposed surfaces of the body—the hands, forearms, and feet. The etiology is a matter of dispute. Ogston[33] grew an almost pure culture of a peculiar micrococcus, called the micrococcus campaneus, from the serum obtained from the sore. Harmon[34] believes the staphylococcus aureus, which has become attenuated in its virulence, to be the cause. Pridmore[35] believes the infection to be carried by the horse tick. The sore may begin in the deep layers of the epidermis and assume the form of a bleb, or its first appearance may be that of an abrasion. The ultimate lesion is a slowly extending chronic ulcer, spreading very gradually at its periphery. It is most amenable to treatment by moist antiseptic dressings.

SPECIFIC ULCERS.—*Syphilis, Chancroid.*—The initial lesion of syphilis and the chancroid have both been described in special articles, so we need refer here only to the symptoms and appearance of secondary and tertiary ulcerative syphilitic lesions. These occur on both the skin and the mucous membranes. When a syphilitic ulcer develops on a mucous membrane it assumes one of two types: the superficial and the deep. The superficial ulcer which involves only the mucous membrane has indurated, slightly elevated, sharply cut, perpendicular, "punched-out" edges, and an indurated base covered with a yellowish film of tenacious secretion. These ulcers arise from mucous patches, deposits of round cells, or "mucous gummata." The deep syphilitic ulcers arise from the breaking down of gummata in the deeper part of the mucous membrane or in the tissues beneath it. They are irregular with an indurated, sloughing base, and ragged undermined edges surrounded by an area of induration. The adjacent tissues may become involved in the syphilitic process and undergo destruction. In this way the cartilage of the nose or of the larynx, or the bones of the hard palate or the nose, may be destroyed. After the healing of a syphilitic ulcer there may have been such a destruction of tissues that strictures of the pharynx, larynx, œsophagus, or rectum ensue.

On the skin three distinct types of syphilitic ulcer are found: the superficial, the serpiginous, and the deep. The *superficial ulcer* may appear comparatively early in the disease. It usually varies in size from a quarter to a half dollar; it has a circular outline, with sharply cut edges, and a dirty-yellowish, purulent base. Several of these ulcers may unite to form an ulcerating area with

DIFFERENT VARIETIES OF ULCERS

a scalloped margin. The superficial form is most frequently found on the face and legs. The *serpiginous ulcer* may originate from a single circular ulcer, which heals at one side, while it progresses at the other; or it may take its origin in the breaking down and coalescence of several tubercles. Subsequently the new tissue thus formed at one part of the ulcer also breaks down. It is on the back, at the junction of the hairy scalp with the face and neck, and on the extremities that the serpiginous ulcer is most frequently found. The *deep ulcers* result from the breaking down of gummata (Plate LVII., Fig. 3). They are at the beginning surrounded by a reddened area of inflammation, the smaller ones being crater-like with punched-out edges, the larger ones having overhanging, thin, soft, inflamed edges. The base is of an angry, dusky-red color, dirty or sloughing in appearance, the slough being often of a greenish color. The discharge is thin, often bloody, and contains débris from the broken-down gumma. Under treatment and after they have existed for some time, they lose their characteristic appearance and take the form of simple chronic ulcers. The scar remaining is characteristic. It is thin, of a dead-white color, pigmented here and there, and when pinched up wrinkles like tissue paper. This form of syphilitic ulcer may occur anywhere on the surface of the body, but is particularly apt to be found on the upper half of the leg. In fact, an ulcer occurring on the upper half of the leg, unless directly due to traumatism, is nearly always syphilitic.

Tuberculosis.—Tuberculous ulcers, like those due to syphilis, occur both on the skin and on the mucous membranes, being more frequent on the latter. When occurring on the mucous membranes they may be primary, but are more often secondary, and are frequently part of a general tuberculosis. They result, as has been mentioned under Pathology, from the breaking down of tubercle tissue. In the mucous membranes of the mouth, tongue, larynx, and pharynx, tuberculous ulcers are as a rule painful, shallow, oval in shape, and irregular in outline. The base is made up of pale, flabby, anæmic granulations. The edges are bevelled and not undermined. The surrounding area is slightly swollen and pale, this pallor of the surrounding tissues being characteristic of tuberculous ulcers of the mucous membranes. These ulcers, although superficial at first, may become deep, and may result in the destruction of the deeper structures by extension of the tuberculous process, as in the larynx. In the intestine the ulcer usually begins by the deposit of tuberculous material in the Peyer's patches or the solitary follicles and the subsequent breaking down of this material. The ulcer is at first small, then becomes larger, irregularly oval in shape, and tends to run transversely around the lumen of the bowel. The edges are slightly elevated, thickened, and not undermined. The base is thickened from the presence of inflammatory and caseous tissue. It is usually roughened and irregular, sometimes sloughing. The process involves all the coats of the intestine, and there is usually a local peritonitis set up on the outer wall of the serous coat, through which white or yellowish tubercles may frequently be seen. In the rectum tuberculous ulcers are irregularly oval, often deep, and there may be a marked infiltration of tubercle tissue about them. They sometimes perforate the wall of the rectum and give rise to the formation of sinuses and fistulæ. In the bladder tuberculous ulcers, when secondary to tuberculous disease of the kidney, are most frequently found about the orifices of the ureters. Ulcerative lesions of the vulva and vagina may be found secondary to tuberculosis of the uterus and adnexa. Lupoid ulceration of the mucous membranes occurs only on those mucous surfaces which are near the natural openings of the body, and usually by extension from without, although cases primary on the mucous membrane have been reported. It occurs on the mouth, tongue, larynx, pharynx, nares, conjunctiva, vulva, vagina, and anus. It has the general characteristics of lupus of the skin, and will be described under this heading in the following paragraph.

On the skin tuberculous ulcers follow five distinct types. *Tuberculosis cutis*, a rare form, occurs almost exclusively about the mucous orifices—mouth, anus, vulva, and glans penis. It is part of a general tuberculosis, but the ulcers are due to local infection. It consists of one or more discrete, shallow, painless ulcers, with a reddish-yellow granular base and an irregularly eroded, moderately infiltrated edge. The discharge is thin and scanty, and is apt to dry and form crusts. When the ulcer extends to a mucous membrane, small yellow miliary tubercles may exist near them. The ulcers never heal and may attain considerable size, and by coalescing with others become serpiginous. *Tuberculosis verrucosa cutis* occurs as one or more brown or livid-red warty patches, ulcerating on the surface, varying in size from about a lentil to a silver half dollar, and surrounded by a narrow zone of erythema. Several patches may unite to form an irregularly shaped lesion, with a scalloped border. Usually there are no subjective symptoms, but there may be slight pain on pressure. It is most frequently found on the hands. *Lupus vulgaris* occurs most frequently on the alæ nasi, at the junction of the skin with the nasal mucous membrane. When an ulcerative lesion occurs, it is preceded and surrounded by small, soft, brownish-red, s nitranslucent tubercles which resemble apple jelly in appearance. These easily break down and ulcerate. The base of the ulcer may be quite superficial and smooth, composed of pale flabby granulations, covered by a crust, or the process may destroy the cartilages and the ulcer become deep and irregular. The edges are sharp, soft, irregular, and eroded, and, when the ulcer is spreading, surrounded by small lupoid tubercles. The development of the disease is very slow. It has a tendency to cicatrize at one portion while spreading at another, and leaves a thin, red, irregular scar, in which new tubercles may form and break down. When an ulcer occurs as a result of *erythema induratum*, it is preceded by a subcutaneous nodule, the skin over which later becomes red, then purple in the centre. If it breaks down, the nodule sloughs or suppurates and leaves a round, excavated ulcer with a grayish base. The edges are not undermined. The lesions are apt to be symmetrical, being most frequently found on the legs, especially on the outer and posterior aspect. The origin of that form of tuberculous ulcer which is known as the *scrofuloderm*, has already been mentioned (Plate LVII., Fig. 6). The base of the ulcers is covered with pale flabby granulations which are often exuberant; its edges are thin, undermined, and of a peculiar livid or violaceous color. The discharge is a thin, sanious pus. Frequently the ulcers are connected with other tuberculous ulcers, or with tuberculous glands, bones, or joints. They are usually painless. When the ulcer has healed the scar left is usually puckered and disfiguring, and is often bridled. Tubercle bacilli may be found in the tissues and discharge of any of the tuberculous ulcers, but they are infrequent, and often in old ulcers cannot be obtained.

Other Specific Ulcers.—The symptoms arising from ulcers due to typhoid, diphtheria, dysentery, leprosy, glanders, actinomycosis, etc., together with those due to certain skin diseases, such as pemphigus, ecthyma, herpes, and eczema, are those rather of the disease than of the ulcer, and the reader is therefore referred to the special articles in this work on these subjects.

Malignant Ulcers.—*Epitheliomatous Ulcer.*—The most frequent form of malignant ulcer is that of epithelioma. It is infrequent under forty years of age. Its usual situations have already been mentioned. The base of the characteristic epitheliomatous ulcer is hard, nodular, and irregular, made up of hard warty granulations and often covered with sloughs. It bleeds easily and has a foul discharge. The edges are hard and everted (Plate LVII., Fig. 4). The amount of pain, the involvement of neighboring lymphatic glands, and the rate of growth vary. Epitheliomata which develop from congenital warts, moles, or nævi are apt to be very malignant. When epitheliomatous degeneration occurs in a chronic ulcer, it begins to get hard about the edges, which become everted and bound down to the deeper tissues. The granulations about the edges become large, red, nodular, hard, and bleed very readily. This condition spreads over the whole ulcer, and it assumes a sloughing and foul character. The tissues immediately surrounding the edges may show a stony-hard induration, due to extension of the malignant process. The diagnosis is confirmed by the microscopical examination of a section cut from the edge of the ulcer.

Rodent Ulcer, or, as it is sometimes called, Jacob's ulcer, is histologically a form of epithelioma, although it may be differentiated from it clinically. It occurs on the upper half of the face, beginning as a small nodule like a wart. Various observers have believed its origin to be in the hair follicles, sebaceous or sweat glands, or the deep layers of the rete. J. M. McFeely[36] states that the deep layers are involved first, but that the disease shows a tendency to avoid the hair follicles. The ulcer grows very slowly. Its base is smooth, glossy, and depressed, being lighter in color than epithelioma (Plate LVII., Fig. 1). The edges are hard from infiltration, smooth and rolled over. The discharge is slight and apt to form crusts. The deeper tissues are not involved until late and the ulcer is movable. There is a tendency toward cicatrization. Caustics retard its growth, while, unless they are thoroughly applied, they stimulate epithelioma. Rodent ulcer never forms metastases, causes cachexia, or involves the lymphatic glands. Auche[37] reports a case of the disease which existed for twenty years without glandular involvement.

Scirrhous Ulcer occurs usually with scirrhous carcinoma of the breast in women over forty. The slow-growing tumor gradually involves the skin, which breaks down and ulcerates. The ulcer is deeply depressed, with a pale pink, smooth base and no granulations. It is intimately adherent to the new growth below; in fact, its base consists of the new growth. There is slight discharge. The edges are raised and very hard, but may be undermined by ulceration. The surrounding skin is often atrophic, wrinkled, and adherent to the new growth. The ulcer increases in size very slowly, as this is a very slowly developing form of carcinoma.

Fungating Ulcer.—Rapidly growing carcinomata and sarcomata, which are near the surface, may either involve the skin or protrude from an operation wound; they form large, foul, exuberant masses composed of cancerous and granulation tissue which are covered with sloughs, bleed easily, and have a foul, sanious discharge. They grow very rapidly (Plate LVII., Fig. 2).

The symptoms caused by malignant ulcers of the mucous membranes would be those of the new growth, and would not be included within the scope of this article.

Ulcers of the Mucous Surfaces.—Besides those forms of ulcer on the mucous membrane which are due to malignant disease and the various specific infections previously mentioned, there occur the ulcerative forms of stomatitis, gastric, duodenal, and other intestinal ulcers, as well as ulcers of the rectum, bladder, vagina, and vulva from various causes. For the symptoms of these, together with the symptoms of ulcer of the cornea, and fissures of the nipple and anus, the reader is referred to the special articles on these subjects.

Differential Diagnosis.

The diagnosis of ulcers does not as a rule present much difficulty, but occasionally it may not be easy to determine the form of ulcer present. To facilitate this a number of tables are given below, showing the points which determine the differential diagnosis of those forms in regard to which confusion is most apt to occur.

Lupoid ulcer and a tuberculous syphilide might easily be confused. From the latter lupus is differentiated by the facts that it usually appears at an early age, that it develops very slowly, that it is characterized by the presence of apple-jelly-like tubercles, that the ulcers are more shallow and have only insignificant crusts, that there is no tendency on the part of the disease to involve the bones, that other syphilitic symptoms are lacking, and finally that potassium iodide produces no benefit.

Complications and Sequelæ.

The most frequent complication of ulcer of the skin is cellulitis. This may sometimes be so severe as to necessitate operation. Erysipelas may also complicate cutaneous ulcers. After the healing of an ulcer the resulting cicatrix may by its contraction cause severe deformity—distortion of the features when the ulcer is upon the face or neck, or partial ankylosis in the case of extensive ulcers, as those resulting from burns, in the neighborhood of a joint. Keloid formation occasionally occurs in the scar resulting from an ulcer. Hemorrhage, especially from a varicose ulcer, is a common complication and has been fatal. Involvement of the lymphatic glands and destruction of the deeper structures (cartilage, bone, muscles, or joints) may occur in malignant, tuberculous, syphilitic, or phagedenic ulcers. The continuous drain on the system from the profuse discharge from an extensive ulcerating surface in a debilitated subject may cause such weakness as to indicate amputation. Malignant ulcers may form metastases in other structures.

In the case of ulcers on the mucous membranes, besides the destruction of the deeper tissues, the complications most common are perforation of the stomach or intestines, and hemorrhage. An actual perforation is frequently prevented by the formation of adhesions due to the localized peritonitis which occurs when the serous coat is involved in the inflammatory process. Strictures are frequent sequelæ to ulceration of the mucous membranes.

Treatment.

The treatment of ulcers is both constitutional and local. The constitutional treatment consists in building up the system by tonics when this is necessary, and in treating those general conditions and diseases which act as direct or predisposing factors in the etiology of the ulcer (such, for example, as the gouty diathesis, arteriosclerosis, diabetes, scurvy, etc.). It is also important to improve the hygienic surroundings, to administer mercury and the iodides for syphilis, to prescribe cod-liver oil, the hypophosphites, and a change of climate for tuberculous conditions, and iron and arsenic for anæmia, etc., thus making it possible to obtain the best results from the local treatment.

Local Treatment.—In considering the subject of local treatment, it must be remembered that there are several things which we should aim to accomplish. These are: (1) the reduction of inflammation in and about the ulcer; (2) the cleansing and sterilization of the ulcer; (3) the stimulation of the granulations; (4) the relief of congestion and the establishment of a proper blood supply; (5) the promotion of new epithelial growth and cicatrization.

Reduction of Inflammation.—Frequently, when an ulcer comes into the hands of the surgeon for treatment, the ulcer and the surrounding tissues are in a state of considerable inflammation and cellulitis. For the reduction of this inflammation and the relief of pain moist dressings are the most effective form of treatment. A solution of alum acetate, made by adding 5 parts of lead acetate and 1 part of alum to 100 parts of water; or a one-per-cent. aqueous solution of ichthyol; or Thiersch's solution (1 part salicylic acid, 5 parts boric acid to 500 parts water)—any one of these solutions applied on a thick gauze compress and kept moist and cool, acts admirably in this condition. The permanent bath of Kaposi,[38] consisting of clean or if possible sterilized water, but containing no antiseptics, acts in the same manner. It has no advantages over the former treatment, except perhaps in the case of ulceration following extensive

Tuberculous, Syphilitic and Epitheliomatous Ulcers, and Rodent Ulcer.

	Tuberculous Ulcer.	Tertiary syphilis.	Epithelioma.	Rodent ulcer.
History	Of previous glandular, bone or lung disease.	Of syphilis	Sometimes of small abrasion or irritation.	Often of wart or papule.
Age	Generally youth	Any age. Most frequently middle life.	Seldom before thirty-five or forty.	Seldom before forty-five or fifty.
Base	Soft, pale, œdematous granulations.	Smooth or sloughy. Apt to be of a dirty-greenish color.	Hard, wart-like granulations. Bleed easily and apt to slough.	Hard, smooth, depressed. May show evidence of cicatrization.
Edges	Thin, undermined, violaceous color.	Punched out or undermined. Dusky red. May heal at one point and advance at another.	Very hard, elevated, nodular, everted.	Hard, sharply cut. Not much elevated.
Glands	Usually involved. Not necessarily secondary to ulcer.	Not involved	Usually in from three to six months.	Not involved or very late.
Course	Slow	Rapid without treatment. Heals with it.	Varies. Malignant	Usually very slow.
Other symptoms	Other signs of tuberculosis—sinuses, bone disease, etc.	Other signs of syphilis	May be cachexia or metastases.	Usually none.

Leg Ulcers.

	Traumatic.	Varicose.	Syphilitic.
History	Injury	Varicose veins or phlebitis	Syphilis.
Situation	Where injury occurred	Usually lower third of leg anteriorly or laterally.	Usually upper third of leg. Often posterior aspect.
Base	Shallow, inflamed, often grayish yellow.	Bluish, pigmented granulations; sluggish. Usually superficial.	Dirty, sloughing; often greenish. Deep.
Edges	Not elevated or thickened	Undermined or thickened. Shape irregular.	Punched out or thin and undermined, deep dusky red. Shape round or serpiginous.
Surrounding area	Red and inflamed	Pigmented. Varicose veins; often œdema and eczema.	Dusky red. Scars of old, syphilitic ulcers.
Healing	Rapid under antiseptic treatment.	Support of veins necessary	Mercury and potassium iodide necessary.

Ulcers of Tongue.

	Chancre.	Tertiary syphilis.	Tuberculosis.	Carcinoma.
Age	Usually before thirty	Usually before forty	Any age. Rare before puberty.	Usually after forty.
History	Sometimes of infection	Previous syphilitic	Usually of pulmonary tuberculosis.	Often of irritation and of cachexia.
Number	Single	Often multiple	Generally single	Single.
Situation	Usually tip or anterior part of edges.	Often mid-line toward median or posterior surface of dorsum.	Usually tip or anterior portion of dorsal surface.	Most common on one side at middle or posterior third.
Shape	Generally round	Round or oval	Sinuous outline or oval	Irregular.
Base	Hard, smooth, superficial	Deeply excavated. Sloughy, not much induration.	Pale, flabby granulations	Hard, irregular, vascular, sloughy, purulent.
Edges	Hard, indurated, sloping	Ragged, irregular, undermined, or sharply cut.	Bevelled. Surrounding area pale.	Raised, everted, thickened, indurated.
Pain	Slight, if any	Slight	Painful	Very painful.
Glands	Subhyoid in six weeks	Usually not	May or may not	Usually in a few months.
Course	Rapid healing with development of secondary syphilis.	Heals with antisyphilitic treatment.	Slow progression. Part of a pulmonary tuberculosis.	Generally rapid. Floor of mouth or pillars of fauces involved. Loss of speech.
Microscope	Round cells	Gummatous tissue	Tubercle bacilli	Carcinoma cells.

burns or gangrene on the trunk, where it is difficult to keep dressings applied.

Cleansing and Sterilization of the Ulcer.—Before healthy granulations can form on an ulcer, the removal of sloughs and cleansing of the base must be accomplished, with as much sterilization as is possible. Many means toward this end may be effective. A one-half to one per cent. solution, or rather emulsion, of creolin, is very useful in cleaning up those extensive, dirty ulcers from which a profuse foul discharge escapes. A one-per-cent. solution of formalin is of great value in cleaning up smaller ulcers, especially those due to tuberculous disease. The destruction and removal of sloughs may be hastened by cauterization with the solid stick of nitrate of silver and the application of iodoform or naphthalin powder, the latter particularly. The use of certain ferments, such as brewers' yeast, papoid, caroid, or protonuclein, may help in the clearing up of a chronic ulcer which shows a tendency toward a croupous condition. The most frequent means employed for the cleansing and sterilization of the ulcer, previous to the application of some stimulating dressing, is washing its surface with bichloride-of-mercury solution (1 in 1,000) or one of carbolic acid (1 in from 40 to 80), or with hydrogen peroxide. In addition to these means of sterilization and also with the aim of promoting healing, Zeimer[39] recommends a one-per-cent. filtered solution of chloride of lime. Colleville[40] suggests that the ulcer be subjected, for a period of from twenty minutes to one hour, to the heat radiated from a plate of metal that has been brought to a dull-red heat, and that is held at a distance of ten inches from the ulcer. Von Langsdorf,[41] recommends the application of calomel and salt, the chlorine from the salt uniting with the calomel to produce bichloride of mercury. This method is often very painful. Tarabrin,[42] employs the Paquelin cautery at a dull red heat, holding it at a distance of 5–6 cm. from the ulcer; nearer if no pain ensues. Bukovsky[43] uses a culture of B. pyocyaneus fourteen or fifteen days old, diluted with a solution of potash and hydrochloric acid. Stone[44] recommends twenty grains of mercurol in one ounce of vaseline. Tshitsherin[45] reports favorable results from the employment of phenosalyl, especially in ulcerating gummata.

Stimulation of the Granulations.—Having reduced the inflammation and succeeded in cleansing the ulcer, the next thing to consider is the means by which granulation may be stimulated. This may be done by applications in the form of powders, solutions, or ointments. In the form of powders are used iodoform, aristol, nosophen, xeroform, orthoform, bismuth subnitrate and subgallate, boric acid, salol, antipyrin, sulphur, charcoal, lycopodium, zinc oxide, and other substances. In the form of solutions one may employ argentic nitrate, zinc and copper sulphate, potassium permanganate, formalin, ichthyol, balsam of Peru, camphor, myrrh, and benzoin. In the form of ointments, zinc oxide, boric acid, ichthyol, mercury, balsam of Peru, Lassar's paste, salicylic acid, and camphor are available. All of these drugs have their advocates. One of the oldest and best of the stimulant applications is balsam of Peru, which has a powerful effect in increasing the growth of granulations; but often, after this has been accomplished, the granulations are apt to become exuberant, with little tendency to cicatrization. In some cases it has considerable irritant action and may cause a dermatitis. Unna[45], twenty years ago, made a study of the action of certain drugs in regard to their effect on granulations. He found that carbolic acid, bichloride of mercury, and salicylic acid favor the growth of granulations, but hindered cicatrization. Iodoform and boric acid favored both, while pyrogallic acid, sulphur, and ichthyol particularly favored the growth of epithelium. The latter drug, which was introduced by Unna,[46] is useful not only for favoring the growth of epithelium, but also for reducing inflammation and stimulating granulations.

When an ulcer is particularly indolent, the application of the solid stick of nitrate of silver, or of solutions of nitrate of silver, zinc, or copper sulphate in strengths of from two to ten per cent., may, by inducing some inflammatory reaction, hasten granulation. The application of antiseptic and astringent powders finds its chief use when the discharge is profuse, the ulcer being covered after the application with a soft absorbent dressing. They may also be applied to advantage when the ulcer is quite small, with so little discharge that it may be healed under a scab. In painful ulcers orthoform is of great value on account of its analgesic action. In the majority of cases the best results are obtained with moist dressings, which, while they stimulate granulation, also absorb the discharge. Balsam of Peru and ichthyol have already been mentioned. In addition to these, one of the most valuable applications for promoting the healing of an ulcer is "red wash," made up after the formula: Zinc sulphate, gr. xx.; compound tincture of lavender, ʒ ss.; distilled water, ℥ viij. This solution has a powerful astringent action and promotes cicatrization, especially when there is a tendency for the granulations to become exuberant. Walbaum[47] recommends the application of wine of camphor under rubber tissue after sterilization of the parts and reduction of inflammation with liquor aluminis acetatis. Kundler[48] has obtained good results in the treatment of chronic ulcers with hot water, using two litres of water as hot as could be borne, and allowing it to fall on the ulcer from a height of six feet. This was repeated two or three times a day, and the procedure was followed by the application of iodoform or dermatol.

In regard to the employment of ointments, it may be said that their use is generally contraindicated where there is a very profuse discharge, as they prevent its absorption by the dressing. It has also been observed that there is often a tendency for the granulations to become soft and flabby under their influence. They are often valuable, however, in combination with the fluid applications, especially where the discharge is small in amount and apt to dry, and also when the ulcer is surrounded by an area of eczema or dermatitis. Under both these circumstances the ulcer may be dressed with gauze soaked in balsam of Peru, red wash, etc., and then, over this and the surrounding area, some form of bland ointment, such as Lassar's paste or zinc oxide ointment, spread on lint, should be applied. When used in this manner the ointment prevents the rapid absorption of the discharge by the underlying dressings and the subsequent drying and irritation of the ulcer; at the same time it exerts a soothing effect upon the surrounding inflamed skin. Schultz[49] strongly recommends the use of camphor in the form of an ointment for chronic leg ulcers. He says: "Of all the remedies, new or old, for ulcer of the leg, camphor gives the best results." He gives two formulæ: (1) Triturated camphor, ʒ ss.; zinc oxide, ʒ viiss.; lard, ad ℥ iv. (2) Triturated camphor, ℥ ss.; zinc oxide, ℥ iij.; and olive oil, ℥ iij.

In addition to the use of the above applications, various other therapeutic measures have been employed for stimulating granulations and promoting healing of chronic ulcers. Oxygen gas has been recommended by Semple.[49] Galvanism and high-frequency electric currents have been used by several since the publication of the cases of Meyer and Blackwood,[50] but apparently they have little to recommend them as being superior to other methods. Heeve[51] reports favorable results in the treatment of chronic leg ulcers by means of the x-ray combined with the brush discharge. Zarabin[52] and others have also cured varicose ulcers by means of the x-ray. The subject of radiotherapy and phototherapy will be taken up in the consideration of the treatment of special forms of ulcer. In a certain number of cases in which there has been a considerable loss of substance, which it is desirable to replace by granulations, the method of sponge grafting, introduced by Hamilton,[53] may be of use. Briefly, this consists in the application of a sterilized piece of sea sponge to the area to be grafted, the aim being to cause the granulations to grow into and fill the spaces in the sponge, which latter is subsequently absorbed, its place being taken by the granulation tissue. Sometimes this is successful, but frequently the sponge acts as an irritating foreign body.

Relief of Congestion and the Establishment of a Proper Blood Supply.—In the case of chronic leg ulcers, and especially those associated with varicose veins, it is impossible to effect a cure until the chronic congestion of the limb is relieved and the blood supply of the part approaches normal. Often all that is necessary is a muslin or flannel bandage properly applied over the dressing, and reaching from the toes to the knee. Volkmann[54] in 1862 first suggested the use, for ulcers of the leg, of occlusive cotton dressings. He used a thick layer of cotton, bandaged on with firm even pressure and left in place until the odor of decomposition appeared. Lister's method was similar to this, only he used protective over the ulcer, after sterilizing it and the limb, and then enveloped the latter in borated cotton. Martin's[55] rubber bandage, when applied with moderate, even pressure, has for its purpose the relief of congestion, but in some cases the rubber has an irritating effect on the skin. Unna's paint as a dressing for chronic leg ulcers is strongly recommended by Michel.[56] It is made from glycerin and water, āā 10 parts, gelatin and white oxide of zinc āā 4 parts. The leg should be cleaned, rubbed with alcohol, and dried thoroughly. The paint is warmed until it becomes fluid, and then it is applied all over the leg, including the ulcer, from the toes to the knee. A wide-meshed gauze bandage is then applied without reverses, care being taken to avoid wrinkles and to exert an even pressure. Over this is then painted another coat of the mixture. When cold the dressing looks and feels like white rubber. If properly applied, such a dressing should last for from four to eight weeks. If there is much discharge, a window may be cut over the ulcer, through which it may be dressed. Gaudin[57] employs a somewhat similar method, using traumatol and starch bandages, so applied as to draw the edges of the ulcer as much together as possible.

When the granulations are almost on a level with the surrounding skin, and also when there is considerable thickening of the edges of the ulcer, the best means of keeping up an even pressure, and causing absorption of the thickened margins, as well as hastening epithelial growth, is to apply zinc oxide adhesive plaster in strips one-half to one inch in width. These strips should overlap to the extent of about one-third of their width, should be evenly and smoothly applied, and should extend about three-fourths of the way around the limb. They should be started about one inch below the ulcer, and should run up one inch above it. When the callosity of the edges is very marked, it can often be made to disappear by the application of a piece of wood or metal a little larger than the ulcer, tightly strapped on so as to overlap and make firm pressure on the edges. In a considerable number of chronic leg ulcers, however, it will be found that the various methods which I have described are inadequate, and that satisfactory results can be attained only by putting the patient to bed and keeping the leg slightly elevated. Probably a great many of the favorable results obtained from the various therapeutic measures so highly recommended by different writers, are largely due to the adoption of the measures last named. It is also necessary in some cases to immobilize the limb when the ulcer is over a joint, for the motion of the latter prevents healing.

When varicose veins are associated with chronic ulcers of the leg, which fail to heal under the above methods of treatment, various operative measures may aid in effecting a cure. Multiple ligation of the veins with or without excision, or ligation of the internal saphenous after the method of Trendelenburg, may, by directing the circulation through the deep veins, relieve the superficial congestion, and aid in effecting a cure in obstinate cases. Wenzel[58] has obtained very favorable results in the cure of varicose ulcer by means of a circular incision at the junction of the lower and middle thirds of the thigh, and the resection of from one-half to one and one-half inches of all the cutaneous veins in the wound. In this connection should be mentioned the operations advocated by several French writers, who believe that the relationship which exists between an ulcer of the leg and varicose veins is effected through the nerves, the degeneration or chronic inflammation of which produces trophic disturbances. Silvy[9] recommends fascicular dissociation of the sciatic nerve. Chipault[59] reports favorable results in cases of chronic ulcer by stretching the musculo-cutaneous, internal saphenous, sciatic, and external popliteal nerves. Thernot[60] reports the cure of a recurrent traumatic ulcer by stretching the external popliteal and saphenous nerves, with resection of the saphenous vein.

Promotion of Cicatrization and New Epithelial Growth.—The value of nitrate of silver and red wash as stimulants of the healing process has already been mentioned. They are also of value in producing cicatrization and promoting the covering of the ulcer with new epithelium. If the solid stick of nitrate of silver be touched very lightly to the edges just inside the pale bluish line of advancing epithelium, so as to produce a white film on the surface, this slight cauterization will be found to aid in strengthening and cornifying the new delicate, previously invisible epithelial cells, and in preventing them from being washed away by the discharge from the ulcer. The solid stick of nitrate of silver is also of value in destroying exuberant granulations which project above the surface of the surrounding skin; and often by piercing these flabby granulations in several places with the solid stick held perpendicular to the surface, cicatrization is hastened. After the granulations are level with the surrounding skin, the covering of the ulcer with new epithelium is hastened by the application of some smooth surface, along which the epithelium can spread. For this purpose zinc oxide adhesive plaster, thin rubber tissue, or protective may be used.

In a number of old chronic cases healing is prevented by the fact that the base of the ulcer cannot contract, owing to its being bound down by fibrous scar tissue. This binding down of the base and edges of the ulcer also tends to cut off the blood supply, and therefore in this additional manner the healing of the ulcer is hindered. For the relief of this condition a number of operations have been devised. Gaffky[61] employed mattress sutures, introduced through the normal skin beyond the edges of the ulcer and passing beneath it, out through the skin on the other side. By tightening these sutures over a button or metal plate the ulcer was lifted from the underlying tissues. Liston[62] introduced the method known as starring of the ulcer. He made a series of radiating incisions through the base and edges of the ulcer, the point from which the incisions radiated corresponding with the centre of the ulcer. In this and in the following operations, in order to obtain a favorable result, it is necessary that the incisions pass completely through the cicatricial tissue that forms the base and edges of the ulcer, into normal tissue. "Cross-hatching" of the base of the ulcer by means of a series of incisions at right angles to each other, and at a distance of about one half inch apart, was suggested by Harbordt,[63] and is often of value in aiding healing of a chronic ulcer, the continued existence of which and failure to heal having been due to its thickened, adherent base and edges. The method of circumcision of the ulcer was introduced by Nussbaum.[64] This consists in making a circular incision around the ulcer, through the normal skin surrounding it. The procedure was modified by Hodgen,[65] who made a series of overlapping, short, curved incisions surrounding the ulcer, instead of the single circular incision. In these last two methods it is necessary that the incisions be made through normal skin, and that the wounds be made to gape—if necessary, by packing them with gauze.

When an ulcer is of considerable size, it is often impossible to secure healing, even by these methods. It may for a time appear as if it were going to heal, and a pale blue line of newly formed epithelium may spread out from the edges; but instead of the epithelium continuing its progress, at a subsequent dressing it will be found to have melted away. In these cases as well as in those in which the size of the ulcer would necessitate a long wait for a cure, or in which the subsequent contraction of the scar (as on the face or palm of the hand, for example) would produce deformity, skin grafting, skin transportation, or some form of plastic flap operation is indicated. The method of Reverdin, as modified by Thiersch,[66] is the one most frequently employed. (For the details of this method see the article on *Skin, Transplantation of.*)

The method of skin transportation, as devised by Wolfe,[67] and also by Lefort,[68] and which was further developed by Esmarch, consists in the use of the whole thickness of the skin, removed from a healthy surface, and tacked down by a few stitches to the edges of the surface to be covered. The advantages which this method possesses over the Thiersch method are these: the cosmetic result is better, the tissues are more elastic, and less contraction takes place. It is, however, much easier to make the Thiersch grafts adhere, and the area from which they have been obtained is easier to heal than if the entire thickness of the skin has been removed. Kellock[70] has suggested a method which consists in a combination of both skin grafting and skin transportation. After marking out an area of skin which is to be removed in its entire thickness, he cuts with a sharp razor, from the skin surrounding the marked-out area, a number of small, thin, superficial grafts, one edge of each being left attached to the margin of that area of skin which is to be removed in its entire thickness. The thin grafts are then reflected up over the central area where the skin is dissected up in its entire thickness, and the fat is removed from its under surface. Thus is obtained a graft, the centre of which consists of the entire thickness of the skin, the margins being only of thin epithelium. When the graft is put in its new position special care must be employed in spreading the thin margins, as they adhere first and retain the whole graft in position. This method has all the advantages of skin transportation, and the new graft is more apt to adhere than when the old methods are used.

The use of plastic flaps was first suggested by Graefe and Maas.[71] In this method a flap of skin from some neighboring part, left attached by a pedicle, is applied to the area to be covered, and after it has become adherent so that it can obtain its nourishment from its new base the pedicle is cut. Flaps may be taken from a part near the area to be covered, or from some other surface of the body. Thus, for example, a flap from one leg may be used to cover an ulcer of the other leg, or, in order to cover a raw surface on the hand or wrist, two parallel incisions may be made on the anterior chest wall, the skin between them detached from the underlying muscle, and the hand passed beneath this flap, where it is held in place by a plaster-of Paris dressing. When it has become adherent the attachments of the flap are gradually divided. Finally, if none of these methods of treatment should prove successful, the question of resection of the part or amputation must be considered.

Special Forms of Ulcer.—The above methods of treatment are those applicable to the usual forms of ulcer. The specific or special forms of ulcer, however, require special treatment. A syphilitic ulcer requires the use of mercury locally as well as mercury and the iodides internally. A tuberculous ulcer is best treated by thorough curetting of the diseased tissue, after which formalin in one- to two-per-cent. solution or iodoform makes the best local application. It is also necessary to build up the system with cod-liver oil, syrup of the iodide of iron, and the hypophosphites. In order to cure a perforating ulcer of the foot, the ulcer must be thoroughly curetted and all dead bone removed from the base of the ulcer. Where the ulcer is a result of constitutional disease, as scurvy, diabetes, or gout, the disease must be treated in order to cure the ulcer.

Malignant ulcer can only be cured by the destruction or removal of the new growth. For the treatment of epitheliomatous ulcers, caustics, with or without curetting, excision, photo- or radiotherapy, may be employed. The best caustics are arsenic, chloride of zinc, caustic potash, and formalin. The objections to this method are the extreme pain, the lack of certainty as to the removal of all of the growth, the fact that the lymphatics and glands are not dealt with, and also that, unless the treatment is thorough, growth is stimulated rather than retarded. The scar is also apt to be unsightly. In most cases excision forms the best method of treatment. The incision should be wide of the ulcer, and all induration of the tissues and any lymphatics or glands which are involved should be removed. Finsen has reported a number of malignant ulcers treated by his light method, some successfully and some not, but since the publication of the cure of a case of rodent ulcer by Sequera,[32] of London, by means of the Roentgen rays, this method has been successfully tested and used all over the world in the treatment of malignant ulcers; especially good results having been reported in the treatment of rodent ulcer by Taylor[33] and others. It cannot be denied, however, that in a certain number of malignant cases this mode of treatment is absolutely without effect. Its particular use is in inoperable cases, and in those in which an operation would leave a badly deforming scar.

It is not necessary to enter deeply into the consideration of the treatment of lupoid ulceration, as it is taken up in another section of this work. The old methods of treatment by excision, scarification, the use of the Paquelin cautery, nitrate of silver, salicylic acid, resorcin, formalin, and calomel injections are still held to by many. Unna[34] has recommended the use of soap containing from five to twenty per cent. tuberculin. Hallopeau[35] recommends permanganate of potassium. Dethlifsen[36] claims excellent results, especially as to the scar, from freezing with ethyl chloride spray; but the treatment of lupus by phototherapy and radiotherapy is now receiving the most attention. Cases are undoubtedly cured by both of these methods. Many, however, are still sceptical as to the permanency of the cure, although Finsen has reported 130 out of 456 cases of lupus treated by his light method, free from recurrence for from one to five years. The objection to the method is the time required for each treatment, the large number of treatments necessary, and the great expense. The *x*-ray treatment, which is less expensive, will, according to Morris and Dore,[37] heal ulcerative lupus more rapidly than the Finsen light, although the latter is more effective in small non-ulcerative conditions. The exact action of the *x*-ray is not known, as it has been found that it does not kill bacteria in cultures, as is done by the Finsen light. But it appears to stimulate normal cell growth at the expense of morbid cells, which, being of lower vitality, are destroyed. Its application has also been shown to cause leucocytosis.

Routine Treatment of Ulcers.—While there can be no routine treatment of ulcers applicable to all cases, it may be of use in conclusion to give briefly the usual method adopted by many of the large clinics in New York city in treating the common forms of leg ulcer. If the ulcer be inflamed, the inflammation is reduced by wet dressings of alum acetate or one-per-cent. solution of ichthyol. After this is accomplished, if the ulcer is still dirty or the discharge profuse, after thorough cleansing with hydrogen peroxide and 1 in 1,000 bichloride of mercury, a one-per-cent. wet dressing of creolin is used. Sloughs are cleaned up with iodoform or naphthalin powder and the granulations stimulated with nitrate of silver. Balsam of Peru is used as a stimulating dressing except when the ulcer is painful, when ichthyol or alum acetate wet dressings are substituted, or a ten-per-cent. ichthyol ointment is applied. When the cavity is almost filled, or when the granulations become exuberant, redwash gauze is substituted for the balsam of Peru, the gauze being covered with a layer of Lassar's paste on lint. And, finally, when the granulations reach the level of the surrounding skin, the edges are very lightly touched with nitrate of silver and adhesive strapping is applied. During the whole treatment maintenance of the limb in an elevated position, for as long a peroid of time as possible, is advised, and a snug, even, muslin pressure-bandage is applied over cotton, from the toes to the knee. Complications or unusual conditions are treated according to the methods previously described. Finally, after a cure has been effected it is always well to instruct the patient in the care of the limb. It is important that he should keep it clean and dry, and if necessary powdered with talcum powder or stearate of zinc, and when varicose veins are present, he should wear an elastic stocking or bandage, thus avoiding a recurrence of the ulcer, which so frequently occurs.

In conclusion, I wish to express my thanks to Drs. B. Farquhar Curtis and W. C. Lusk for the use of photographs of their cases, and to Drs. W. S. Schley and F. O. Virgin for their aid in obtaining the other photographs.

John Douglas.

ADDENDUM TO ARTICLE ON TYPHOID FEVER.

(*See page 926.*)

Dr. Wright's latest reports (*British Medical Journal*, October 10th, 1903) are exhibited in the following tables:

TABLE I.—SHOWING THE INCIDENCE OF AND DEATH RATE FROM TYPHOID FEVER IN THE BRITISH ARMY IN INDIA DURING THE YEAR 1901.

	Average strength during the year.	Cases of typhoid fever.	Deaths from typhoid fever.	Incidence rate. Per cent.	Death rate. Per cent.
Uninoculated ...	55,955	744	199	1.33	0.36
Inoculated......	4,883	32	3	.66	.06

This table shows that antityphoid inoculation diminished the incidence rate of typhoid fever by one-half and the death rate by five-sixths.

TABLE II.—SHOWING THE INCIDENCE OF TYPHOID FEVER IN LORD METHUEN'S COLUMN AT THE MODDER RIVER, SOUTH AFRICA, FROM DECEMBER, 1899, TO MARCH, 1900.

	Number.	Cases of typhoid fever.	Incidence rate. Per cent.
Uninoculated	10,981	257	2.3
Inoculated.........	2,535	26	1.0

It will be noted that the table testifies to a diminution of the incidence rate by more than half during the period of observation.

Dr. Wright infers from the testimony of Table I., and from his own previous personal experience with inoculation in India, that the *minimum* duration of protection afforded by antityphoid inoculation is three years.—*G. B. S.*

END OF VOLUME VII.
